ORIGINAL ARTICLES.

THE TREATMENT OF THORACIC ANEURISM BY IODIDE OF POTASSIUM.[1]

BY R. L. MACDONNELL, B.A., M.D.,
PROFESSOR OF HYGIENE IN MCGILL UNIVERSITY, PHYSICIAN TO THE MONTREAL GENERAL HOSPITAL.

THE good results afforded by the treatment of thoracic aneurism by moderate doses of iodide of potassium deserve more favorable recognition by the profession, on whose part there is a tendency to regard aneurism in the chest as a disease wholly incurable and almost beyond relief. As a consequence such cases often appear at city hospitals to take advantage of a treatment which in many instances could have been carried out at home with equal benefit, and certainly with less expense and discomfort. Of the various plans of treatment which have been proposed, none has proved so satisfactory as that of rest with the administration of iodide of potash. No special diet restrictions need be carried out. The amount of food daily consumed should be moderate, and the daily allowance of fluids kept within comfortable limits. Rest in bed is not an absolute necessity, except when symptoms are urgent, and when cough and dyspnœa are severe, or where it is evident that a very rapid growth is taking place in the tumor.

Eighteen cases of thoracic aneurism have come under my observation during four years' service on the medical staff of the Montreal General Hospital. Not all of these were my own cases, but some were under the care of my colleagues, with whose kind permission I quote them. All were not available for proof of the efficacy of any kind of treatment, the majority refusing to stay in the hospital, or leaving in a few days, whilst others who were out-patients could only be induced to remain long enough to be examined by the clinical medicine class. There remain but six cases to illustrate the beneficial results of the iodide of potash.

CASE I.—D. J., æt. fifty-five, colored, a barber, admitted in December, 1885, with symptoms of extensive aortic enlargement, there being pressure symptoms showing that the whole arch as well as the descending aorta was involved. A pulsating prominence dull on percussion was found in the left interscapular region: orthopnœa; brassy cough and severe pain in the left chest; cardiac area much increased; double aortic murmur. The case is elsewhere reported in detail to record a rare symptom in aneurism of the chest, viz., localized sweating over the area of distribution of those nerves supposed to be pressed upon by the tumor. This man steadily improved under treatment, went to his home in June, 1886, and has remained ever since in a greatly improved state of health. He is no longer confined to bed, can walk about the house, or short distances in the street, without discomfort or pain. The tumor has become smaller and pulsation less evident. He has been taking iodide of potash in ten grain doses almost uninterruptedly since he first came under observation.

CASE II.—G. C., æt. thirty-five, about three months ago began to suffer from cough of a hollow, dry, brassy character, and extensive pain under the upper part of the sternum. There was urgent dyspnœa upon exertion. Tracheal tugging was present. There was no dulness on percussion or bruit. Aneurism probably in the transverse arch pressing upon the trachea. No history of syphilis.

After six weeks' residence in hospital, taking ten grain doses of the iodide, he returned to the country. The pain and dyspnœa were relieved, but cough was still present. No further history to be obtained.

CASE III.—E. A., æt. forty-seven, for twenty years a cavalry soldier and instructor in sword exercise. Admitted to the hospital for the first time in June, 1885, complaining of pain in chest, dyspnœa, dry brassy cough without expectoration, emaciation and debility. Had syphilis ten years ago. Dates the present illness from the kick of a horse received in January, 1885.

The pain is very severe, situated in the upper sternal region and shooting to the right side, becoming intolerable on any attempt to lie on the left side. The superficial veins are enlarged upon the chest and left side of the abdomen. There is local bulging with expansile movement and dulness on percussion over an area one and a half to two inches in diameter, at the level of the second rib, close to the right side of the sternum. No thrill; no murmur; second sound accentuated. No tracheal tugging; carotid and radial pulses are equal. Paralysis of left vocal cord.

Was placed upon ordinary diet, and given ten grains of iodide of potash three times a day.

[1] Portion of a paper read before the Canada Medical Association at Hamilton, Ontario, Sept. 1, 1887.

After a month it was noted that he had gained flesh, the brassiness of the cough had almost disappeared, there was no dyspnœa, and he became able to lie upon either side without pain or distress. He was discharged in September, 1885. Not finding any work to do he joined the volunteers and undertook night duty for a week in the guarding of public buildings at the time of the vaccination riots, and being anxious to make money he took duty for others, so that he was on guard every night in succession for a week. Then he obtained a situation as groom, which he was able to keep, until he found something better to do in the cotton factories at Cornwall. On Nov. 23, 1886, he returned to the Montreal General Hospital with an attack of facial erysipelas. He told us then that he had almost uninterruptedly taken the iodide, and that he had not suffered any of the symptoms for which he had previously been under treatment. He is active and well now (Dec. 12, 1887).

It is commonly stated, and, indeed, by some of the best authorities on the subject, that the benefit derived from the iodide is entirely due to the accompanying rest and diet, but I think here the drug must get the credit.[1] This man was enabled by its use to be relieved of symptoms and to return to the gaining of his living, continuing, as far as we know, for two and a half years in good health, doing hard work and under no diet restriction.

Case IV.—I. G., æt. fifty-four, was a man whom the world had used hardly. He had been a soldier in the Royal Artillery and was wounded by a bayonet thrust through the back of the neck at Inkerman, was made prisoner by the Sepoys in India, lost his right leg in an explosion in a mine, and broke his right thigh in a railway accident. Admitted to the Montreal General Hospital on the 27th of November, 1886. Had been complaining of hoarseness for nearly a year and had been under treatment for an affection of the throat. Last September, two months before admission, had been suddenly seized with a severe paroxysm of coughing, and since then had suffered greatly from a dry, hard cough, which was worse at night or upon exertion. Latterly, there had been severe pain in the chest and dyspnœa upon the slightest exertion, so urgent as to prevent the patient walking even a short distance, or talking without getting completely out of breath. When quite at rest the breathing was very noisy, so much so as to disturb other patients in the ward. The voice was reduced to a whisper. Suffered from sharp pain shooting up the right side of the neck to the occiput. History of syphilis very probable.

The physical signs pointed to the presence of an aneurism of the innominate.

The symptoms were very severe and alarming; nevertheless, steady improvement followed the use of iodide of potassium. He stayed in hospital all winter, being at first obliged to remain in bed owing to the dyspnœa, but after two months improvement was most evident; pain, dyspnœa, and cough disappeared. From March to May he was kept on as a convalescent, assisting in the work of the hospital, and not suffering from any of his symptoms, except the noisy breathing, which was noticed only when he was asleep. On the day of his discharge, in May, he was able to walk from the hospital to my house, a good mile up hill all the way, without any suffering.

Since that time I have not seen him, but I hear that he is still alive.

Case V.—W. H., æt. thirty-one, had been from boyhood a bandsman in the Imperial Army, and had served many years in India, but has lately been employed as a lumberman. Has had acute rheumatism but never any venereal disease. Admitted to Montreal General Hospital on Dec. 15, 1885, under the care of Dr. George Ross, complaining of a painful lump in the upper part of his chest. About a year previously to admission he began to suffer from pain supposed to be neuralgic, in the upper part of the chest, in the right axillary region, and along the inner side of the upper arm. After a time these pains became less severe, and were succeeded by others in the right side of the head and neck, which soon attacked the other side. When pain first appeared a dry hacking cough began, which gradually has been increasing in severity, and soon was noticed to have a barking sound. Shortness of breath upon exertion has never been present. One month ago he noticed the swelling in the chest.

Physical examination (extract from Hospital Case-book): A well-nourished, healthy-looking man, temperature normal; pulse 72, good strength, regular, equal on both sides. On the front of the chest a distinct pulsating elevation 1½ inch in diameter, seen at the upper part of the sternum, reaching as high as the sterno-clavicular articulation, and lying a little to the right of the middle line. Percussion shows a dull area of a diameter of 2½ inches, the centre being the centre of the tumor. Pulsation in the tumor is well marked, heaving and lateral, and there is a well-marked diastolic shock, but no thrill. In the episternal pit pulsation is slightly felt. There is a slight soft blowing systolic bruit of maximum intensity to the right of the tumor, transmitted out beneath the right clavicle, very faintly heard over the tumor, increased by sitting posture and variable in intensity from time to time. The second sound is loud and booming over

[1] Gull (Lancet, Nov. 27, 1875): "Those cases of reputed aneurism, which were said to be cured by iodide of potassium, were really not aneurisms at all. They were examples of mistaken diagnosis."

the tumor and usually distinct at the apex. Tracheal tugging is well marked.

The usual ten grains of the iodide were prescribed with rest in bed and good diet.

Dec. 31. Aneurism has decreased one inch in circumference; pulsations less strong; bruit louder. The bony edge of the aperture in the sternum can be clearly felt. No pain whatever.

Patient left the hospital. There remains but a very slightly elevated tumor at the upper part of the sternum with evenly distributed pulsation with maximum force at the upper part of the sternum and toward the right, where a well-defined hole in the bone can be made out, through which the impulse can be more plainly felt. Dulness on percussion remains over an area of about two and a half inches in diameter.

No report has been heard of the course of the disease.

CASE VI.—H. M., æt. forty-three, now a laborer but for many years a sailor. Admitted Oct. 2, 1885. The disease began with pain in the right side of the neck and head, which has occurred off and on for a long time, and which he dates from a strain in lifting a large piece of ice some nine years ago. No history of syphilis. In 1884 the pains became worse, the voice hoarse, and he began to lose flesh, signs of pressure on the superior vena cava began to appear, the lids became puffy, the face and neck greatly swollen, ears blue. Dyspnœa on exertion was also present. There were physical signs pointing to the presence of an innominate aneurism. The abdominal and thoracic veins on the right side were enlarged. Tracheal tugging present. Right pupil smaller than the left; no paralysis of the vocal cord.

Treatment as usual. He left the hospital on the 4th of October taking his medicine with him, returning on the 23d of the same month to report himself. The face and lids were much less swollen. Pain partially relieved, cough easier. Dyspnœa has been troublesome on one occasion only. Has been sleeping well, which he has not done for twelve months. He was readmitted on Oct. 30th, and discharged in January, 1886, feeling much better with the exception of a return of the pain, but he soon came back with symptoms no worse, but there was noticed for the first time deficient resonance over nearly the whole of the left lung, with weakened breathing. For the rest of the winter he remained in the hospital, nearly all the time in bed, complaining of the dyspnœa at night, but in June, 1886, he improved greatly and left us. Now here occurred what I consider remarkable in the case: this man who had been so ill all winter, and in extreme suffering and danger, so far recovered as to be able to leave the hospital, obtain work, and gain his living for seven months as a night watchman. In September, I saw him walking in the street, looking as well as any one, a man who but a few months before had been in bed gasping for breath, blue in the face, and lying propped up with pillows. He told me that he himself was so convinced of the benefit of the iodide that nothing would tempt him to miss a dose of it, and that he had persistently taken it since he had been in hospital. When the winter came on he got out of work, and having no home suffered great hardships. I found him one day in the early winter half clad and hungry wandering about the streets, and secured his admission to the hospital, but rather too late. The privations of the last few weeks seemed to have undone all that had been done. Rapid enlargement of the superficial thoracic veins took place, and he died in hospital.

CASE VII.—This case is introduced to show the immediate effects of iodide of potash in relieving urgent symptoms.

W. S., æt. forty-eight, a private patient, now a clerk, who has served twenty-one years in the army, fourteen years in the ranks and seven as a military clerk. Had syphilis severely twenty years ago. Has had symptoms of aneurism for seven years, pain in right shoulder and root of the neck and shooting into the tips of the fingers, and was treated for rheumatism in a military hospital, whence he went to St. George's Hospital, where the diagnosis of aneurism of the innominate was first made. In 1882 he was subjected to a course of low feeding with iodide of potassium in thirty grain doses. The pain was very severe and numbness in the arm was also present. About this time the right clavicle became dislocated forward and the pressure symptoms abated.

When I saw him there was very great dyspnœa and most severe pain in the chest, the general condition being one of angina. Could not lie down or remain quiet for any length of time. There were physical signs of a very large aneurism of the innominate artery extending above the dislocated clavicle into the root of the neck. Right pupil was much smaller than the left, and the right pulse much weaker than that of the other side. He had been suffering severely from pain and dyspnœa for the previous six weeks.

Immediate relief was afforded by morphia and the patient given the usual dose of iodide in spite of his protestations. At the end of a fortnight all urgent symptoms had disappeared, and he was enabled to return to his duties suffering no pain. He remained well, under my observation, until May, 1886, when he lost his situation and went to the west. During all this time he had no symptom to complain of, and repeatedly told me that he had not felt better since the aneurism began.

FEMALE DRESS AS A DETERMINING FACTOR IN PULMONARY CONSUMPTION.

BY THOMAS J. MAYS, M.D.,

PROFESSOR OF DISEASES OF THE CHEST IN THE PHILADELPHIA POLYCLINIC.

However much the human family may pride itself on the independence of its mental forces, it is quite certain that its physical constitution is moulded to an indefinite extent both by external and internal influences. Food, drink, clothing, shelter, ventilation, occupation, exercise, sexual differentiation, etc., not only modify the conditions of normal life, but render the two sexes liable to different diseases. The fact that a greater liability exists in the female sex toward hysteria, chorea, cancer, anæmia, ascites, peritonitis, glaucoma, etc., and in the male sex toward angina pectoris, tetanus, locomotor ataxy, Addison's disease, diabetes, typhoid fever, etc., are evidences of the general truthfulness of this statement, and we shall herein offer evidence to show that pulmonary consumption is no exception to this rule.

It is currently believed that more females than males fall victims to this disease. Both Laennec and Louis held this view, at least so far as France was concerned; and Ancell, one of the most prolific and exhaustive writers on the natural history of tuberculosis, concurs entirely in this opinion. Sir James Clark's statistics, which were collected from thirteen different localities in Europe and America, showed in the aggregate more deaths from phthisis among females than among males. Dr. A. James, in an interesting article on "Sex in Connection with Phthisis," lately published in *The Edinburgh Medical Journal* (March, 1886), arrives at the same conclusion. It must be admitted, too, that if the question of sex in relation to pulmonary consumption be viewed from an *a priori* standpoint, there are sufficient reasons for believing that the female is more prone to the disease than the male, because she is generally considered to be the weaker, and because she is more exposed to the causes which are known to give rise to it. She is confined within-doors, where she naturally spends the greater portion of her life, and is, of course, subjected to the influences of impure air and bad ventilation. She leads a sedentary life, is deprived of sunlight, exercise, and undergoes the enervating processes of gestation and lactation, while, on the other hand, the male is, as a general rule, less or not at all exposed to most of such unhealthful conditions; and it is only when he is subjected to some of them, as, for instance, to impure air, sedentary occupations, etc., that he becomes notoriously liable to pulmonary consumption.

Having recently made an inquiry into the death-rate of pulmonary consumption in different parts of this city,[1] our attention, in comparing the death-rate of this with that of some other American cities, was drawn to the fact that in most instances the male decedents from consumption exceeded the number of female decedents. The range of the statistics which we then examined was rather too limited to draw any satisfactory inferences, and it therefore appeared to us of interest to ascertain whether this difference in the liability of the two sexes to this disease exists with sufficient constancy to be regarded as a law, and, if so, whether there be any obvious cause for this phenomenon. We accordingly collected and herewith present statistics in regard to this question which embrace the principal cities of Europe and of America, as well as some of the agricultural districts of the former country, besides embodying statistics of about six thousand cases of consumption which have been gathered from the hospitals and private practices of various authors and practitioners throughout Europe and America. We have, so far as this was possible, compared the number of deaths from consumption of each sex with

the population of each sex living at the time, and in those cases where such a comparison could not be made, as, for instance, in those which were culled from private and public experience, the number of each sex treated is simply stated. In many cities, a larger number of females than of males die of consumption, but with a very few exceptions it appears that the proportionate death-rate from consumption is less among the female than among the male population because, as a rule, here the females outnumber the males.

The statistics which we have collected on this subject are presented in the following order: (1) the reports of health boards, etc., and (2) cases of consumption which have been treated by various practitioners of medicine.

These statistics, which were not selected but comprise all which we were able to examine, so far as they go, establish the fact, beyond a doubt, that in civilized life the male sex is more liable to pulmonary consumption than the female sex. It is true that some instances show exceptions to this rule; but when we, on the other hand, take into consideration that, in these, the mortality difference is slight, and that the great mass of evidence points overwhelmingly in the other direction, the conclusion we have stated becomes inevitable. The hospital statistics presented above likewise point out the same preponderance of the male element in the morbidity and mortality rate of pulmonary consumption. It is well known that, as a general rule, more females present themselves at clinics, dispensaries, and hospitals, than males, yet in all of the returns here given a disparity is shown in favor of the female sex so far as pulmonary consumption is concerned. Thus, an analysis of the clinic record of the Chest Department of the Philadelphia Polyclinic, with which we have been connected, from January 1, 1885, to date, shows that during that time there appeared for treatment 1741 patients, most of whom suffered from pulmonary or cardiac diseases, or from affections allied therewith. Of this number 754 were males, and 987 were females. It will be seen, however, that while the females outnumbered the males in the general chest clinic, the number of males predominated among the consumptives—for of these there were 113 males against 88 females.

Now, the question which naturally presents itself here is, as to whether this greater liability of the male sex to pulmonary consumption is merely the result of chance or accident, or whether it is governed by causes which are as persistent as the phenomenon is regular. We believe that a line of difference so strongly and so clearly drawn as this is cannot be the product of fortuitous circumstances only, and that the cause for its existence is in a great measure inherent in the functional differences which obtain in the breathing of the two sexes.

Since the time of Boerhaave[1] it is known that a fundamental difference exists between male and female breathing, that the former breathes chiefly with the lower portion of the chest—which is called the diaphragmatic or abdominal type of breathing; and that the latter breathes principally with the upper portion of the chest, which is called the costal type of breathing. These types of respiration can be graphically illustrated on a registering cylinder by means of a pneumograph as is shown by the following tracings. The first is a typical tracing of male, and the second a typical tracing of female respiration (see Figs. 1 and 2). The first half of each tracing represents the abdominal, and the second half the costal movements. This order will be observed in all the tracings which appear in this paper unless otherwise indicated.

It will be observed that the contrast between a typical male and female respiration is well brought out by this method of demonstration, the curves of the tracing showing the greatest amplitude in the abdominal and the least in the costal movements of the male, while in those of the female this order is exactly reversed.

Quite recently, and with a view of establishing whether this difference of respiratory motion in the

[1] Prælect. Academ., § 623, tom. v. p. 144. Ed. Haller., Amst. 1744.

civilized male and female is primitive or acquired, we had the privilege given to us of investigating the chest' movements of the Indian girls of the Lincoln Institution of this city. All the girls in this school had been brought here in their wild condition, and their bodies had not yet been subjected to the constricting influence of civilized dress, hence it is obvious that such an observation would give us a true representation of the chest movements in their original state. In all we examined the movements of eighty-two chests, and in each case took an abdominal and a costal tracing, of which the following is a typical example (Fig. 3). When the tracing is compared with that which is obtained from the chest of the civilized female (see Fig. 2) it will be observed that a most marked modification has taken place in the movements of the female thorax during the transition period from savage to civilized life. A complete reversal of the type of respiration has taken place; the abdominal type of the Indian becoming the costal type of the civilized female. That this change of type has been effected principally through the influence of civilized dress, and not through the influence of gestation, as was believed by Hutchinson and others, is shown by the following considerations:

1. The costal breathing is much less apparent, and the abdominal breathing is more pronounced in those civilized adult females who have never worn corsets, than in those females accustomed to the use of corsets. This is well shown in Fig. 4, which is a tracing of the respiratory movements of one of those rare specimens of the female sex who has never been invested by a corset.

2. The costal type of respiration is more marked both in the civilized and in the Indian female when the abdominal constriction is tight, and it is less in the civilized, and wanting in the Indian female if the abdominal movements are not restrained by tight dress. Fig. 2 is a typical tracing of the abdominal and costal breathing of a civilized female clad in corset and dress ordinarily tight. Fig. 5 is a tracing of the breathing of the same female after the corset and constricting dress had been removed. We have found that a similar variation in the respiratory

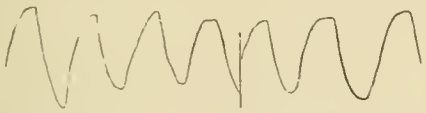
movements of the full-blooded Indian female takes place when her abdominal respiration is interfered with by a constriction.

3. The costal breathing, as a rule, is much more evident in those Indian females who have a mixture of white blood in their veins, than it is in those of pure Indian stock, thus showing, too, that the influence of inheritance plays a part in the modification of the chest movements.

4. The chest movements in the male can be vastly modified by placing a broad band around the abdomen sufficiently tight to interfere with the motion of the diaphragm. Fig. 6 is a tracing of the movements of a male chest after the abdomen was tightly bound with a strong and inelastic belt. In order to observe the modifications which can be thus produced, this figure is to be compared with Fig. 1.

FIG. 6.



Tracing of chest of civilized male, with tight belt around abdomen.

These data demonstrate, then, that the primitive type of respiration in both male and female was abdominal, and that the costal type of respiration which is characteristic of the civilized female differentiated from the original type through the influence of dress. If, therefore, the chest movements are thus readily moulded, even at the will of the experimenter, as has been shown, it becomes an important question to determine whether the influence of dress plays any part, either direct or indirect, in the production of this disease under consideration, both in the male and in the female sex.

When we look into the history of the natural genesis of pulmonary consumption, we find that almost without exception it starts in the apex of either lung. This fact becomes pregnant with forebodings so far as the cause of this disease is concerned, when it is taken in connection with the other fact that the lungs possess a much greater air capacity than is necessary to meet the oxygen demand of the blood, and to carry off the effete products of respiration under the ordinary conditions and surroundings of life. The truth of this is not only confirmed by the many known instances in which persons having large cavities in their lungs, and who are thus deprived of a considerable portion of their breathing surface, are considered well enough for all practical intents and purposes; but also in the many instances in which cavities have been found after death in persons who died from some other cause than consumption, and who were never suspected of having had a process of excavation going on in their lungs during life. The best proof, however, of the correctness of the proposition that the lung-surface is larger than is necessary for the proper aëration of the blood is the experimental evidence[1] which has been recently adduced by Prof. Mosso, of Turin, Italy. The experiment consisted in counting the number of respirations in a given time, and in measuring the amount of air taken in during each respiration by means of an air-clock which was constructed for the purpose, and which through a well fitted mask was connected with the mouth and nose. Observations were made at the sea level, and at different mountain elevations, and it was found that at an elevation of about 10,000 feet the amount of air inspired was nearly twenty-five per cent. less than at the sea level, and although the respirations nearly doubled themselves in frequency, they also became more shallow.

These experiments show then that at or near the sea level man breathes about one-fourth more air than is utilized in his body. This Professor Mosso calls "luxus-athmung" (excessive respiration), and by a similar experiment he shows that the number of ordinary respirations can be reduced to nearly one-half their frequency without entailing much bodily inconvenience at the time. While the possession of such a luxus-respiration, and of the voluntary power to diminish the respiratory frequency to such a great degree, and with apparent impunity, are wise provisions of nature to meet the requirements of many exigencies in life, they are also great elements of danger, and are liable to become a prolific cause of pulmonary consumption. For it is evident that if the blood would consume all the oxygen which is supplied to it during ordinary respiration, the slightest interference with the breathing function would at once manifest itself by a feeling of air-hunger which would stimulate the respiratory function to renewed activity. But this not being the case, it is likewise clear, on the other hand, that in many conditions of life the function of breathing is greatly diminished from sheer force of circumstances, and to the ultimate detriment of the respiratory organ, as we shall see in what follows.

When from any cause such a diminution of the breathing function takes place it is obvious that, if the air reaches all parts of the lungs with equal facility, the diminished activity will be distributed equally throughout these organs and no special part will suffer. This is impossible, however, for on account of a peculiar downward direction of the bronchial tubes there is an unequal expansion during each inspiratory act. The base and middle parts of the lungs always expand before, and always more

[1] Periodische Athmung und Luxus-athmung, von Professor Angelo Mosso, in Turin, Archiv für Physiologie. Du Bois Reymond, Supplement Band (December 8, 1886), p. 37.

completely than the apices, hence the apices are normally the most inactive and the worst ventilated areas in the respiratory organs.

This question therefore arises, What connection is there between the inactivity of the apex and its liability to the beginnings of pulmonary consumption? How does inactivity prepare the apex for the onset of this disease? This can be best answered by stating that inactivity of a whole or a part of an organ implies that its individual or component parts are likewise inactive. The elastic and muscular fibres of the lungs, which assist in expanding and in contracting the pulmonary air-cavities, the arterial and venous capillaries, which serve as channels in which the blood is aërated, the processes of respiration, assimilation, and nutrition are all involved in the affected area.

Now, it becomes no difficult matter to foretell the probable pathological consequences which will follow such a condition as this! It is well known that when a lung, or a part of a lung, suffers in the discharge of its functions, as, for instance, in the acquired or congenital form of atelectasy, a contraction of its elastic tissue fibres occurs which of necessity not only reduces the bulk of the affected spot, but also the calibre of the bloodvessels, thus interfering with the capillary circulation to a degree which ultimately leads to hyperæmia and perchance to a rupture of the bloodvessels of the part. Such a contraction of the lung parenchyma, which undoubtedly takes place, too, in the incipient stage of pulmonary phthisis, serves to explain why it is that long before an active outbreak of the disease, the apex shrinks in volume, and why the lung then admits air with difficulty, as is evinced by a blowing inspiration over the implicated area.

Moreover, it may be stated that, as a rule, all who suffer from consumption of an apex, also suffer from a want of proper expansibility of the overlying chest wall. Indeed, we may say that in our experience we never saw a case in which this was not true at the very onset of the disease. It must not be overlooked, however, that after the disease has passed its first stage, and when serious destruction of the lung tissue is taking place, the respirations become deeper and more active in order that the diminished respiratory surface may satisfy the air-want of the body. This, however, is a direct result of the waste of pulmonary tissue, and the fact remains that all consumptives at the beginning of the disease, or those who have a predisposition to the disease, show a decided tendency to immobility of the upper part of the chest. We have taken a number of tracings of the chest movements of persons who were in the incipient stage of the disease and never failed to find that the costal motion was very much reduced in amplitude both in the male and female sex. Fig. 7 is a typical tracing of the chest of a female while suffering from slight infiltration of the left apex at the time it was taken.

Fig. 7.

Abdominal. Costal.

Tracing of chest of civilized female with corset on, suffering from incipient consumption.

It will be observed that the amplitude of the costal tracing differs but very little from that of the abdominal tracing. If the tracing of this figure is compared with that of Fig. 2, which is a typical tracing of a normal female chest, the difference becomes apparent.

If we now draw a picture of the incipiency of pulmonary consumption from its clinical side we are led to the very same conclusion. Physically it may be said that the first sign of apex trouble is a prolonged expiration, associated with or without dulness. This denotes either a slight condensation or congestion of the subjacent lung tissue. Or, on the other hand, these signs may be accompanied by crepitation, hæmoptysis, and a few moist râles. How often does it happen that a patient comes to his physician in great haste and in a perfectly demoralized mental condition, saying, "Doctor, I have no cough, no expectoration, and I feel as well as ever I did in my life, but this morning I spat up some blood. Do you think it comes from my lungs?" On inquiry it will probably be found that the patient is following a sedentary occupation within doors, seldom takes much exercise, does not eat as well as formerly, and has been slightly losing in weight, but shows no other abnormal symptom. Physical examination discloses a slight impaired percussion resonance, a prolonged expiration, and a few clicks in the right apex. There is much reason to believe that, if the close dependency between cause and effect above outlined holds true, in this case the patient's destiny would have been greatly changed if he had led an active outdoor life, and had taken care to develop the capacity of his chest instead of stunting it by a stooping position which his vocation demanded of him. This is not an overdrawn picture.

Examination of any mortality table will reveal the fact that pulmonary consumption claims its largest number of victims from that class of employés who spend their days within doors, and who cramp their chest by a sitting posture. Again, there is no doubt that the hemorrhage from which many of such patients suffer is simply due to a rupture of the overstrained and hyperæmic capillaries, consequent on a partial impermeability of that portion of the lung surface from which the hæmoptysis emanates, and may be regarded as an indirect bene-

fit rather than an injury, on account of the relief which it affords to the overdistended circulation.

Having seen then that in the aggregate more civilized males than females die of pulmonary consumption; that the costal respiration of the civilized female is developed through the constricting influence of dress around the abdomen; that the lungs possess an excessive breathing surface which by sedentary occupations, etc., can be, and is frequently reduced in a great degree; that the baneful results of such a reduction, consisting of hyperæmia, etc., fall with the greatest force on the apex of the lung; that all those who suffer from consumption also show a decided tendency to immobility of the upper part of the chest, are we not, therefore, justified in believing that a defective costal respiration and the beginning of pulmonary consumption stand in relation to each other as cause and effect? And, going one step further, is it not clear, that the civilized female owes her greater immunity from this disease, in a great measure, to the fact that she possesses a more highly developed costal expansion? If these relations exist it is quite obvious that her manner of dress is a direct factor in bringing about this result. She has, by force of necessity, been led to clothe herself after a method which demands a restriction of the abdominal and diaphragmatic movements, and which cultivates a greater development of the costal portion of the breathing organs, and, thereby, she unconsciously protects herself to a greater degree against this disease; while the male, on the other hand, dresses himself after a fashion which secures perfect freedom of motion to the diaphragm and to the abdominal muscles, but which also attracts and tends to confine the respiratory function to the lower portion of the chest. Moreover, it must not be forgotten that the same fashion also demands that his clothing should be suspended from the shoulders, which of itself restricts the movements of the upper portion of the chest; making it evident, therefore, that his clothing renders him, both indirectly and directly, more liable to the disease under consideration. To this conclusion, and to no other, do our facts and reasoning lead.

In connection with this part of our subject it would be interesting to trace the relative liability of the two sexes of the civilized and of the uncivilized races to pulmonary consumption, if the necessary data were at hand; for if the peculiar dress of the civilized female diminishes her susceptibility to this disease, then the uncivilized female, who wears no or very little constriction around her abdomen, ought, if other things are equal, to be more liable to it than her more fortunate sister, and ought also to show at least as high, or a higher death-rate than the male of her own race. That the death-rate from consumption among the reservation Indians, or among those who have but recently come in contact with civilization, is much higher than that of the civilized race, we have shown in a previous communication,[1] but whether the uncivilized female is more prone to this disease than the uncivilized male is not so certain. Dr. O. G. Given, physician to the Indian school at Carlisle, who has enjoyed an extensive medical experience among the Indians, states in a private letter to us "that among the Indians, as a general thing, the women are less subject to consumption than the men. The men, as a rule, are not so well developed, physically, as the women, and are the drones of the Indian camp, while the women are the working bees." This statement, which is also corroborated by other testimony, is very important, inasmuch as it demonstrates that the domestic relation between the Indian male and female is the very reverse of that which exists between the civilized male and female. In civilized life the male leads the active industrious life, while in the uncivilized community the female constitutes the energetic factor; she for the most part cultivates the crops and sustains the family, while the male sinks into a state of idleness and crime from which he readily merges into disease. Under these circumstances it would be aimless work to attempt a comparison. Evidence is not wanting to show us, however, that when these people are taken out of their wild haunts, and when the two sexes are brought into analogous relative positions to those which are held by the civilized sexes—*i. e.*, when they are housed, fed, and clothed like their civilized brethren, and when they are engaged in similar pursuits—there is very little difference in the death-rate from consumption. This opinion is based on a limited number of statistics which we extracted from the annual reports of the Indian Schools in Philadelphia, Carlisle, Pa., and Hampton, Va.; covering a period of three years in the first school, and five years in the two last instances—all of which show that, on the whole, the liability of the two sexes to consumption is about equal.

So far as this question affects the negro race our limited statistics show as marked a difference in the liability of the two sexes to consumption as that which obtains in the white race. These people have, however, been so long in contact with the higher form of civilization that their bodies have also, in a great measure, been moulded by the influence of the mode of dress which they copied from their white deliverers. From a considerable number of observations on the chest movements of adult colored females we find that in the majority of instances the costal expansion, while not fully equal to that of the white female, is still quite largely developed. The only noticeable difference, not so markedly shown

[1] Does Pulmonary Consumption tend to Exterminate the American Indian? By Thomas J. Mays, M.D. New York Medical Journal, May 7, 1887.

in the white female, is that, when the abdominal constriction is removed in those colored females who are accustomed to wear tight dress, the costal breathing is less and the abdominal breathing more prominent than when this is not removed; while in the colored female children, who have been subjected to very little abdominal constriction, there is, as a rule, a greater conspicuousness of the abdominal breathing, showing, probably in both cases, a greater tendency to revert to the original type of breathing than in the white female.

The evidence which has thus far been gathered from statistical, experimental, and inductive grounds all tends to demonstrate that impairment of the respiratory movements of the upper portion of the lungs is one of the principal direct causes of pulmonary consumption. Indeed, all the proof goes to show that in many conditions of life, especially in many of those to which the male sex is exposed, the apices of the lungs become superfluous parts of the body, and, on this account, possess a strong tendency to that premature waste which is characteristic of all organs when they fall into a state of inactivity. The practical solution of the problem of the prevention of pulmonary consumption, as well as of the cure in many cases, therefore consists in the adoption of measures which tend to increase the chest capacity, and which maintain the general and local health of the individual.

The treatment, so far as prevention is concerned, resolves itself into a proper exercise of the chest muscles, into systematic breathing, and into the rational employment of compressed and rarefied air; but since it is our purpose to treat the prevention of this disease with more fulness in a succeeding contribution, we shall only briefly touch upon the most salient points of the subject in this paper. First, then, as to a *proper training of the chest muscles.* This is accomplished by raising the shoulders, and by swinging the arms backward, forward, and upward, either with or without dumbbells, or by exercising on parallel bars, care being taken that a full inspiration is taken every time that the arms are thrown backward and upward, or the body forward, and that a complete expiration occurs when the arms are brought together in front, or when the body is thrown backward. These movements should be performed regularly, and from sixteen to twenty times in a minute. There are a number of appliances in the market which are worked by means of ropes, weights, and pulleys, and which are admirably adapted for the enhancement of the above-described movements. They are very simple, and can be attached to the wall of the nursery or of the sleeping-room, and not only afford a healthful exercise, but a pleasant amusement for both children and adults. These exercises should be employed every morning and evening, and from fifteen to twenty minutes, or even longer at a time, but they should never be pushed to fatigue.

Second—Sytematic breathing. Deep, voluntary breathing should be encouraged and practised on every occasion, not continuously, but at intervals throughout the day. This should be done in the counting-room, in the workshop, in the home, and out of doors. Care, of course, should be taken that the air is inhaled only through the nose, especially in the open air, so that the latter is fairly warmed before it reaches the lungs. The breathing should occur at natural and regular intervals of from fifteen to twenty times in a minute. Walking, running, dancing, jumping rope, etc., will add materially to the efficacy of this method of respiration.

Third.—Compressed and rarefied air. Of all the means which have come into use for the purpose of developing the lung capacity, we are convinced that none exceeds in value that of the inhalation of compressed and exhalation into rarefied air. We have devised a pneumatic apparatus, somewhat after that of Weil, which answers this purpose effectually. It is manufactured by Mr. James Wilson, chief of the optical department in Wanamaker's depot. The method produces such a powerful physiological impression that it has already earned for itself a permanent place among the important measures of pulmonary therapeutics. When the individual thus breathes out of compressed air, and breathes into rarefied air successively, the whole chest and especially the apices will procure more perfect ventilation than can be obtained by any other known procedure. The following tracings (Figs. 8 and 9), when compared with the costal tracing of Fig. 1, demonstrate this: Fig. 8 is a tracing of the costal movements,

Fig. 8.

Tracing of the costal movements of a male chest during forced respiration.

when forced during voluntary efforts, and Fig. 9 is that of the same movements while inhaling com-

Fig. 9.

The same movements while inhaling compressed and exhaling into rarefied air.

pressed and exhaling into rarefied air. The greater amplitude of the tracings in the latter indicates deeper, slower, and more complete breathing.

The evidence which has thus far been brought together goes to show that a want of expansibility of the lung apices is one of the most fruitful sources of pulmonary mischief, and that the most effectual means of prevention lie in the methods which tend to oppose this condition. The problem of prevention is not one, however, which can be solved in a short time; but the exercises must be pursued to such an extent that their effects will become a part of the function of respiration; and not until this is properly understood and faithfully carried out will pulmonary consumption begin to lose its terror, and cease to spread death and desolation in our homes.

1829 SPRUCE STREET, PHILADELPHIA,
November 18, 1887.

THE VALUE OF ACETANILID IN ENTERIC FEVER.

BY J. HOWELL WAY, M.D.,
OF WAYNESVILLE, N. C

PERHAPS never before in the history of scientific medicine have new pharmaceutical products been received with that degree of avidity, and so readily given an extended trial in the treatment of disease as the recently introduced antipyretics, antipyrin and its more powerful congener acetanilid or antifebrin. Starting from the place of its discovery in Germany, little more than three years since, the use of the former of these agents spread quickly through the great hospitals and the larger cities of Europe and America, until to-day one can scarcely find a village or hamlet whose medical faculty are not conversant with its therapeutic use.

And while not quite a year has passed since Cahn and Hepp, after studying its effects in Kussmaul's wards at Strasburg, gave to the medical world a full account of their observations on the effects of acetanilid, based on its use in sixty cases,[1] yet in this brief time its use has become, perhaps, as widely extended as that of antipyrin. The uncertainty, and ofttimes inefficiency, of quinine, kairin, chinolin, etc., as antipyretics, and the risks of fatal cardiac depression necessarily attendant on the use of veratrum, aconite, digitalis, and other remedies that lowered pyrexia by reducing the power of the circulatory forces, in doses sufficient to produce decided antipyretic effects, had wrought in the minds of many of the profession the impression that, save the use of cold, we possessed no antipyretic that was efficient, safe, and reliable, no agent which would certainly reduce hyperpyrexia without the introduction into the case of elements of danger often more serious in their nature than a moderate degree of fever heat. Using the language of personification in reference to these new antipyretics, we may say here was indeed their therapeutic opportunity, and their claims were pressed with that degree of enthusiasm usually attending the introduction of new remedial agents.

Observing the extended use of these recent additions to our therapeutic armamentarium, the question —Have these agents fulfilled the reasonable expectations of the profession or not?—naturally suggests itself. Without attempting to reply to this query as a whole, I shall in this paper limit myself to a brief consideration of the value of acetanilid or antifebrin, in the treatment of one of the most important of the febrile affections namely, typhoid or enteric fever.

When I first began the use of antifebrin, I bore with me the painful remembrance of a severe case of typhoid fever which had been doing well up to the end of the second week of the disease, when it came under my observation. During the early part of the third week, the temperature, which had been usually rising during the evening exacerbation to 104.5° F., rose to 105.4° F. one afternoon. Thinking here was an admirable opportunity of giving antipyrin a trial, it was administered as recommended by Brunton,[1] in "thirty grain doses hourly for three hours." The temperature, as taken for me by an attendant one hour after the administration of the last dose, was 96° F.! An hour later, on visiting my patient, I found him in a condition of extreme collapse, and, despite the most active stimulation, he succumbed in less than six hours after receiving the last dose of antipyrin. Afterward I never witnessed any evil effects from the drug, though using it frequently, but in greatly reduced doses, never giving it in larger amounts than ten grains. And while Cahn and Hepp[2] claimed, as a deduction from experiments on the lower animals, that fully two hundred grains would be required to produce a fatal issue in a healthy man, and had themselves given to human beings sixty grains per day of acetanilid without noting any ill effects, from my experience with antipyrin, I was not prepared to accept unreservedly the dictum of authority, but began the use of antifebrin by administering it in small doses of from two to four grains.

During the present autumn I have treated in private practice thirteen cases of enteric fever after the following general plan of treatment, with some slight variations to suit individual cases. When seen during the first few days of the disease, a sharp mercurial purge was induced, and afterward, when necessary, the frequency of the motions was regulated by the administration of opium. This, however, was rarely the case, as in the majority of the cases of enteric fever met with here the diarrhœa does not often become so aggravated as to demand treatment

[1] Berliner klin. Wochenschrift, Nos. 1 and 2, 1887.

[1] Pharm., Mat. Med., and Therap., 1885, p. 696.
[2] Op. cit.

especially directed to it. If not seen early, the mercurial was omitted. From the establishing of the diagnosis until the subsidence of the fever, quinine was given in two grain doses every four hours. Antifebrin was given as follows: in eight cases, two grain doses were administered at 1 P.M. and again at 5 P.M. In two of these cases it was found necessary to give another two grain dose at 9 P.M. In three cases the antifebrin was given in one and a half grain doses at 1 P.M. and at 5 P.M.; and in one of them the same amount was given again at 9 P.M. One of the two remaining cases had three grain doses at 1 P.M., and at 5 P.M.; the other received two one grain doses per day, at 1 P.M., and at 5 P.M. In about one-half of the cases cold sponging was resorted to from three to six times per day.

The highest point of febrile range reached in the evening exacerbation of any of the cases was 106.2° F.; the lowest 103.5° F., the average temperature in the evening exacerbation of the cases was 104.4° F. This observation was made in each case on a day at the close of the second week, when the disease was at its height; the antifebrin being suspended one day for this special purpose.

All of the cases made good recoveries; the average duration of the fever was twenty-two days. The patients were all young persons, ranging in age from fifteen to thirty-seven years; eight were males, and five females. In none of the cases were the slightest evil effects observed to follow the use of the acetanilid, save in a single instance where the patient complained of a slight degree of chilliness coming on soon after the drug was taken. In this case after reducing the dose from two grains to half that amount the temperature was satisfactorily reduced and the chilliness was not experienced. In every case the use of the drug in the doses indicated above invariably wrought a reduction in the temperature of from 1.8° F. to 3.4° F. The average reduction of temperature by the use of acetanilid in the thirteen cases as obtained by a comparison of the temperature of one day when the disease was at its height, and the temperature under the influence of antifebrin, with the day on which the administration of the drug was suspended, was 2.4° F. The effects of acetanilid on the cardiac action were frequently and carefully noted from day to day, and at no time were evidences of weakness or debility attributed to its use observed.

Per contra, I found that, regarding the cardiac condition, less need for the use of alcoholics arose during the progress of the disease than in cases treated after the most approved methods of a year or two past. In addition to this the degree of muscular prostration and exhaustion was not so marked as I have noticed when pursuing the methods of treatment recommended in our standard text-books. These results are, of course, readily explained by the efficient action of the acetanilid in lowering the temperature, thereby lessening the tendency to, and the amount of, granular degeneration of the muscular tissues very much more than in cases treated by the older methods, under which the febrile range could not be so readily controlled.

After the first few doses of the drug were administered in a case it was always noted that patients when fully cognizant of their surroundings, looked forward with interest to the hour for taking the antifebrin, alleging that it made them feel much more comfortable; and it was a matter of daily observation that the muttering delirium was invariably quieted, and the patients often sank into a peaceful slumber when the antifebrin began to produce its effect.

Though, perhaps, the number of cases observed may be too few to justify such a conclusion, I am constrained to believe that in acetanilid we possess our most valuable agent in the treatment of enteric fever attended with hyperpyrexia. Like other valuable agents, its use is likely to be abused, and when injudiciously administered it may prove a two-edged sword cutting for evil as well as good. The reports of cases of cardiac failure and collapse which have recently been appearing in the columns of various journals have, generally speaking, had their origin in the improper and injudicious administration of the drug, *i. e., from the administration of the toxic and not the medicinal dose of the drug.*

In conclusion the following advantages may, I think, be claimed with justice for antifebrin over all other antipyretics in the management of the hyperpyrexia of enteric fever.

1. The size of the dose is small and from the bland and unirritating character of the drug is easy of administration and not liable to produce gastric irritation.

2. The happy effect of the drug in reducing hypernormal temperature and in rendering the patient more comfortable by its soothing effects on the erethitic state of the nervous system accompanying febrile processes.

3. The absolute safety of acetanilid when used in medicinal doses. This conclusion may at present be called into question, but I am fully convinced that when we cease to give our patients *toxic* doses of the drug that cases of collapse and cardiac failure will cease to be observed.

MEDICAL PROGRESS.

Treatment of Empyema without Resection of the Ribs. —At a recent meeting of the Chicago Medical Society Dr. E. Fletcher Ingals described his method of

draining the chest in empyema, without resection, as follows:

The method that I have used in introducing drainage tubes would, perhaps, be of some interest. At present I use a broad flat trocar that is wide enough to allow the introduction of two of these tubes at once, that is, two tubes with an inside diameter of one-eighth inch. First making a very small opening in the skin with a scalpel, the trocar is then plunged in the cavity, and as the stylet is withdrawn, I place my thumb over the canula to stop the flow of pus; the tubes that have been prepared beforehand, are then slipped rapidly through the canula to the required depth, and the canula is at once withdrawn. No air will have entered the chest and not more than two ounces of pus will have escaped. To make the tubes I take a piece of two feet in length, cut it half way across near the middle, fold it on itself and stitch the two sides together so that the tubes can be spread apart in the chest. In one of these tubes I make openings for about four inches, in the other one or two openings close to its extremity. The outer ends of the tubes are tied tightly so that the pus will not flow till I am ready to fasten in the tubes. I cut off two half-inch sections from the same tubing and pass through each two bits of string, the ends of which are tied in loops; these are carried over the drainage tubes down to the surface of the chest; long strips of adhesive plaster are then passed through the loop and fastened to the chest, when the tubes will be firmly fixed. I then carry a roller bandage around the chest over the strips and the dressing is complete. If the patient is in good condition, I then attach to each drainage tube, by means of a bit of glass tubing, longer sections of tubing which have been filled with water, that can reach to the bottom of a basin of water sitting on the floor; the strings which have fastened the ends of the drainage tube are then cut and the pus allowed to escape, or such part of it as is deemed advisable. I recall one case in which I am satisfied if I had allowed any quantity of pus to escape at first it would have been fatal. On one or two occasions I did allow more to escape than was desirable, and I had to inject water into the chest to replace it.

The after-treatment that I have employed consists mainly in washing out the chest twice a day with a solution of carbolic acid, 2 per cent., at 100° F.—*Journal of the American Medical Association*, December 17, 1887.

When Shall Digitalis not be Given?—HUCHARD describes cardiac paralysis produced by digitalis as *digitalis asystolie*, and affirms that by the improper use of the drug it may be grafted upon valvular *asystolie*. This accident may occur

1. When the cardiac muscle is extensively degenerated; digitalis, by its failure to secure response of the heart-muscle, is a valuable means of diagnosticating this condition.

2. There are two stages of the modifications which the viscera undergo in heart diseases; one is the stage of venous engorgement, without marked parenchymatous changes; the other is the stage of sclerosis.

In the first of these conditions digitalis is of great value; in the second, it is most harmful.

When digitalis is contraindicated, Huchard employs caffeine, in doses of from fifteen to twenty-five grains daily.—*Revue Clinique et de Thérap.*, Dec. 8, 1887.

The Abortive Treatment of Buboes.—MANNINO has treated twenty-seven cases of bubo successfully by injecting them every two days with a very small amount of one per cent. solution of corrosive sublimate. A few drops of pus are aspirated at first, and replaced by a few drops of sublimate solution.—*Wiener medizinische Presse*, No. 47, 1887.

Intestinal Antisepsis in Typhoid Fever.—BOUCHARD has found the following formulæ useful in typhoid fever:

An iodoform mixture.

Iodoform.	gr. 9.
Æther. sulphuric.	ʒ 17½.
Carbo. vegetab. pulver. . . .	ʒ 50.

Mix, and after the ether has evaporated, add

Glycerin.	ʒ 45.

Of this, a teaspoonful may be given every two hours in half a glass of lemonade.

Iodoform, in powder, may be given as follows:

Carbo. ligni. pulv.	ʒ 25.
Æther. sulphur.	ʒ 17½.
Iodoform.	gr. 15

The iodoform must be dissolved in ether, and the charcoal added. Dose, a teaspoonful.

A salicylate of bismuth powder may be prepared as follows:

Carbon.	ʒ 12½.
Sacchar.	ʒ 6¼.
Naphthol. (β)	gr. 40.
Bismuth. salicylat. . . .	gr. 40.—M.

To be taken during twenty-four hours.—*Le Bulletin Médical*, December 7, 1887.

Laryngeal Tuberculosis.—ARIZA, of Barcelona, is quoted as follows by the *Journal of Laryngology* for December, 1887, in his experience in this disease: Out of twenty phthisical patients seen by Ariza during the term 1885–1886, in the *Instituto de Terapéutica Operatoria de Madrid*, sixteen were men and four women; their ages ranged between sixteen and sixty-four years. The etiological causes were unknown, but in nearly all the cases there was some pathological relation between the larynx and the lungs. The cause of the affection was always chronic in the first-named organ, while chronicism and acuteness varied in the lungs. Ariza maintains the curability of laryngeal tuberculosis when the lung is sound or only slightly affected, though the lesions of the larynx may compel tracheotomy; and he records the case of a lady patient who, after having been tracheotomized, had an absorptive fever, with copious sweating, purulent expectoration with detritus of the tissues, and pieces of necrosed cartilage, until a time arrived at which the elimination of the tuberculous engorgements ended, and the patient was cured of her laryngitis. The forms of tuberculosis observed in twenty patients were the hypertrophic, the polypous, and the ulcerative. The treatment consisted in touching the ulcers with iodoform, carbolized and boric solutions, as well as with lactic acid and nitrate of silver; in removing the pediculated polypi, and in cauterizing the sessile ones with chromic acid or galvanocautery, and using for hypertrophies galvano-caustic punctures.

A New Preparation of Iron.—CHICAUDARD has prepared the sulphate of the protoxide of iron and ammonia as follows:

He dissolved separately 139 parts of sulphate of iron and 66 of sulphate of ammonia in as little water as possible, at 104° F. He mixed the solutions in a glass vessel, and added a few drops of sulphuric acid and stirred well with a glass rod.

The salt precipitates in small, greenish-white crystals. It is soluble to the extent of seventeen or fifteen per cent. in water. Chicaudard regards this salt of iron as a new and convenient one for physician's use.—*Journal de Médecine*, December 4, 1887.

Ergotin in Suppositories in the Treatment of Uterine Fibromata.—BELL has found the following suppository convenient in administering ergotin for uterine fibromata:

Ergotin	gr. 4 to 8.
Ol. theobrom.	gr. 25.
Vaselin.	gr. 5.

To be used per rectum.

These suppositories are also convenient in menorrhagia and metritis.—*Gazette de Gynécologie*, December 1, 1887.

The Influence of Antipyrin upon Nutrition.—At a recent meeting of the Academy of Médecine of Paris, ROBIN read a paper upon the influence of antipyrin on nutrition. His conclusions are as follows: Antipyrin limits the metabolism of the nervous system, thus limiting its excitability. It diminishes organic disintegration and oxidation, producing a corresponding relative excess of uric acid and nitrogenous waste. Antipyrin possesses antiseptic properties, proved in the living organism and in the laboratory.

From these conclusions he deduces the following clinical indications: Antipyrin is of value in neuroses; its value in fevers is not permanent; its antiseptic value, in very moderate doses, indicates its use in phthisis.

VERNEUIL added the report of two cases of septicæmia, following surgical operation, in which antipyrin, in thirty grain doses, morning and evening, was of the greatest value.—*L'Union Médicale*, December 8, 1887.

The Micrococcus of Beri-beri.—DR. C. A. PEKELHARING, of Atchin, after many attempts and successive failures, has succeeded in making plate cultures of microorganisms from cases of beri-beri; they are in appearance like diplococci, and form a milk-white smooth layer on the surface of agar-agar, which becomes very slowly liquefied. With the culture several rabbits and dogs were inoculated by means of injections under the skin or into the abdominal cavity, or by merely sprinkling the liquid culture about in the cage where the animals were kept. Most of those so treated became affected. One rabbit died nine days after the first of four injections with symptoms of paralysis of the respiratory apparatus and of the hind feet; another rabbit, which was given five injections, died thirty days after the first injection, and much less nerve degeneration was found than in the first rabbit. The animals were always injected several times, as Dr. Pekelharing believed that only repeated doses of the beri-beri poison were usually sufficient to induce the disease, persons who merely visited a barrack where the disease seemed to be endemic not being affected. It is important to note that considerable degeneration was found in the nerves of the hind feet of animals which had during life merely exhibited a slowness of movement. It was found possible to infect animals by injecting bacteria obtained from the air of a barrack where the disease was prevalent, and in these animals the characteristic micrococci and nerve degeneration were observed. This shows the importance of purifying the air of places where the disease occurs.—*British Medical Journal*, Nov. 26, 1887.

For Pulmonary Phthisis.—SCHOULL has obtained good results from

R.—Creasot.	gr. ¾.
Iodoform.	gr. ⅙.
Sodii arseniat.	gr. $\frac{1}{30}$.
Boraginis	gr. ¾.
Benzoin, Magnesiæ	āā q. s.

in pill form, taken with meals.—*Gazette Hebdomadaire*, November 25, 1887.

Removal of a Spoon from the Small Intestine; Recovery.—DR. WALKER reported, at a recent meeting of the Cincinnati Academy of Medicine, the case of a sword-swallower, who, on a wager, swallowed a spoon. It gave him no annoyance for three and one-half years, when it passed from the stomach, and became impacted in the intestine. To relieve the well-marked symptoms of intestinal occlusion, the following operation was performed:

An incision was made in the median line about two inches in length, below the umbilicus. The tissues were divided down to the peritoneum. At the point where the hard body could be felt, there had been great inflammatory thickening. With the needle of a hypodermatic syringe the spoon was plainly felt through this thickened mass. A small incision was made directly over the point where the spoon was situated, as shown by the needle, through this new formed tissue, and a probe passed in to find the direction the gut took. This incision was then enlarged and the handle of the spoon presented. By a slow lateral motion the bowl of the spoon was loosened, and, finally, after some coaxing, was removed. The spoon was six inches in length, the breadth of the bowl was an inch, and the length two and one-quarter inches. After the removal of the spoon, the wound in the bowel was sewed up with three silk sutures. The external wound was closed with silver wire. The wound was dressed antiseptically. The bowel and the tissues adherent to it made the wall of the bowel fully one-half of an inch thick at this point. The peritoneal cavity was not opened at all in the operation. The dangers of it, of course, were therefore much lessened.

After the operation the patient did well. The temperature never was above 100°. The pain in the abdomen was immediately relieved. The bladder trouble disappeared. The stitches were removed on the sixth day, union having taken place. On the seventh day fecal matter began to be discharged from the wound. This kept up for nine days, when the fistula closed again. On the eighth day after the operation the patient had a large operation. The feces contained no blood. The patient was discharged from the hospital—well. What was most feared, a contraction of the canal at the point of incision,

did not occur. The patient has regular stools, and is as well as he ever was.—*Cincinnati Lancet-Clinic*, December 10, 1887.

Naphthalin for Chronic Cystitis.—In addition to the evidence already reported of the value of this substance, the surgeons of the Hospital Necker, in Paris, have recently obtained excellent results by giving naphthalin in powder, in quantities of from 8 to 20 grains to 30 grains in twenty-four hours. It is best given in doses of 1½ to 3 grains, combined with equal parts of sugar, and flavored with an alcoholic preparation of peppermint.—*L'Abeille Médicale*, November 21, 1887.

The Results of the Treatment of Prolapsus Uteri by Colporrhaphy.—The results of this mode of treatment among the German gynecologists, as reported at the recent Wiesbaden meeting, were as follows: 105 cases of prolapsus uteri were treated in five years time in SCHRÖDER'S practice and in his clinic. 88 of these cases were treated in the clinic, and 17 were private patients. The suture material used was catgut, prepared in oil of juniper. Of 123 colporrhaphies, made for various causes, and in which catgut was used, 97 healed by first intention; 24 had an unimportant defect in union; 2 did not heal because of infection. Of the cases of prolapsus uteri, 80 were healed; 2 died; the remainder either showed a bad result or went from observation. In 60 of the clinical cases (88 in all) the subsequent history of the patient was ascertained to determine the question of relapse. It was found that in 23 of the 60 clinical cases a return of the prolapsus uteri occurred. In 13 private cases only 1 showed a return. In the 105 cases 2 died, 1 from chronic nephritis; 1 from marasmus. Of all the cases, clinical and private, operated upon, 67.5 per cent. recovered. Of clinical cases 57 per cent. were cured; of private cases 86.7 per cent. recovered.

The results were reported by members of the clinical staff of the late Professor Schröder.—*Therapeutische Monatshefte*, November, 1887.

For Inhalation in Phthisis.—FILLEAU and PETIT have found the following a most useful preparation for inhalation:

Acid. carbolic.	gr. 30.
Essent. terebinth.	℥ 12½.
Essent. picis	℥ 5.
Eucalyptol. (Merck)	℥ 7½.
Chloroform.	gtt. 5.

Inhalations of five minutes each are advised, four or six times daily.—*Revue de Thérapeutique*, December 1, 1887.

Scrofulosis and Tuberculosis in Children.—NODDECHEN is quoted by the *Centralblatt für Kinderheilkunde*, No. 19, 1887, in the following conclusions, from a series of extended articles:

1. Scrofulosis and tuberculosis are not identical; scrofulosis is hereditary, and not infectious; tuberculosis is infectious, and not hereditary.

2. Scrofulosis is the best condition for the development of tuberculosis; when, in scrofulous tuberculosis, tubercle bacilli are found, we have to do with tuberculosis.

3. The relationship of the bacillus to broken-down, cheesy scrofulous matter, and the fact that by the injection of scrofulous pus tubercle is produced, are as yet not explained; we must believe, however, in the causal relation of the bacillus.

4. Hereditary scrofulosis and hereditary tendency to tuberculosis are identical.

5. If tubercle bacillus fail to find access, scrofulosis may recover; this happens not infrequently.

6. Tuberculosis may be produced by direct infection, without preëxisting scrofulosis.

Iodol in Surgery among Children.—DEMME is quoted by the *Archives of Pediatrics* for November, 1887, as using iodol as follows, among children:

1. As a powder to be sprinkled over deep wounds, for example, after scraping away tuberculous deposits.

2. Upon ulcerative necrotic surfaces, such as may be produced by extensive burns.

3. As a powder to be sprinkled over fresh incised or lacerated wounds.

The wounds are subsequently covered with a dressing of boric lint, over which is a layer of cotton-wool. The dressing is renewed every two to five days, and it has usually been found that the secretions are odorless, and the granulations healthy in appearance. Compared with iodoform, it does not become encrusted with the secretions like the latter, which is sometimes detached with difficulty, and may excite hemorrhage. In removing the iodol from a wound it is best to wash it away with a one per cent. solution of carbolic acid, or a two per cent. solution of boric acid. Tampons of cotton or of borated lint charged with oil of iodol or iodolated glycerin in the proportion of one of iodol to two or four of glycerin may be used to fill cavities which have been opened and scraped. Iodolated gauze of the same percentage strength and similarly prepared as iodoform gauze may be used as a substitute for the latter. Under the use of this gauze the granulation process progresses more satisfactorily than with the use of the oil of iodol or the iodolated glycerin. No symptoms of poisoning nor any harmful effects upon the digestive organs were observed from the use of the iodol. In two cases of extensive burns in which a large quantity of the iodolated glycerin was used, iodine was recovered from the urine one and a half hours after its use was begun. The local antiseptic action of the iodol appears to consist in the permanent separation of a very small quantity of iodine at the surface of application. Before or after absorption more or less of it probably combines with certain alkalies and albuminoids. It is not proper to lose sight of the possibility that the system may undergo toxic effects from iodol in the same way that it does from iodoform.

Geoline.—From *Il Progresso Medico*, we learn that this substance has been used by the ophthalmologists in the hospitals of Naples, and that it has proved a satisfactory base for ointments. It is made from petroleum; is pale yellow; transparent; odorless; containing no fatty matter; is neutral; does not crystallize or oxidize; is not altered by heat, cold, or acids. It melts at 113° F., and combines easily with metals and alkalies.

Antifebrin in Severe Variola.—HAAS, of Prague, has studied the effect of antifebrin in severe cases of confluent variola, and found that in comparatively small doses anti-

febrin lowered temperature, relieved the nervous disturbances of the disease, and prevented in some degree the extensive injuries to the tissues occurring in the worst cases.—*Wiener medizinische Presse*, No. 47, 1887.

Valerianate of Atropia in Whooping-cough.—MICHÉA prescribes, with good results:

Infus. buchu	℥ 30.
Syrup. balsam. tolut.	℥ 2½.
Atropiæ valerian.	gr. $\frac{1}{60}$.

A teaspoonful hourly, as needed.—*Revue de Thérapeutique*, December 1, 1887.

Cocaine a Hæmostatic in Rhino-surgery.—RUAULT is quoted by the *Journal of Laryngology* for December, 1887, as follows, on this subject:

Cocaine is not merely a local anæsthetic, but also a local vaso-constrictor, for the lessening in volume of the nasal mucous membrane produced by this agent is owing to the rapid depletion of the submucous erectile tissue. These two properties of cocaine are independent of one another; the disappearance of sensibility is not due to local anæmia, since tissues deprived of vessels—*e.g.*, the turbinated bodies—are rendered anæsthetic with the greatest ease. The vaso-constrictor result is not due to direct action on the vessels; Bosworth has noticed that this action is confined to the venous sinuses, and does not extend to the capillaries. Indeed, cocaine does not make the nasal mucosa any paler than before the application, and it is, therefore, probable that this loss of blood is due to a reflex action making itself felt on the small arteries and the smooth fibres of the erectile tissue. Ruault has employed cocaine for two years as a hæmostatic, and uses solutions of twenty per cent. to thirty per cent.; he soaks a plug of cotton-wool in the fluid, and leaves it in the nasal cavities for at least nine minutes. In spontaneous epistaxis the plug should be left in for two or three hours. The author has stopped thus a certain number of hemorrhages: one of the patients had been obliged previously to submit to tampons. The use of cocaine also arrests the hemorrhage following nasal operations—*e.g.*, ablation of polypi.

Extirpation of the Larynx.—SIR MORELL MACKENZIE, in the *Journal of Laryngology* for December, 1887, has collected 103 cases of extirpation of the larynx for carcinoma, 8 cases for sarcoma, and 6 for other causes, a total of 117. Of these, 12, or about ten per cent., lived twelve months after the operation.

Cases of Excision of the Tongue for Cancer.—BERNAYS, of St. Louis, reports in the *St. Louis Medical and Surgical Journal* for December, 1887, three cases of excision of the tongue for cancer, of which two made good recoveries; one died of septic pneumonia.

The operations were performed after Kocher's method, and under full antisepsis.

The Treatment of Uræmia.—LANCEREAUX prescribes, to favor the secretion of urine,

Pulv. scillæ,	
Pulv. scammon.,	
Pulv. digital.	āā gr. ¼.

In one pill.

From four to six may be taken daily for from five to six days.

ROLAND prefers the following combination, which acts on all the emunctories:

Ext. jaborandi (alcohol),	
Ext. scillæ,	
Resin. jalap.,	
Resin. scammon. . . .	āā gr. ¼.

In one pill.

Four or five pills may be taken daily, for several days. If preferred, nitrate of pilocarpine may be substituted for jaborandi, in doses of from $\frac{1}{35}$th to $\frac{1}{75}$th of a grain.—*Revue de Clinique et de Thérapeutique*, Dec. 8, 1887.

The Absence of Microbes in Expired Air.—At a recent meeting of the Academy of Sciences of Paris on December 5, 1887, STRAUSS and DUBREUILH reported a series of bacteriological experiments upon expired air. They confirm the result arrived at by Tyndall, that expired air is *optically* pure, and add the further fact that expired air contains no microbes. Grancher, Charrin, and Karth have failed to find tubercle bacilli in expired air from phthisical patients. The fact seems to be that the lungs act as filters, gases being freely expired, but particles being retained. The observations of Pasteur, Lemaire, and Miquel, that microbes are abundant where human beings congregate, is explained by the fact that these microbes are derived from dried sputa, filth upon garments, and dejecta.—*L'Union Medicale*, December 10, 1887.

Iodine Trichloride.—LANGENBUCH has used this powder (ICl_3) as an antiseptic and disinfectant, in solution 1 to 1000 and 1500, which is equal to 4 per cent. of carbolic acid solution, and 1 to 1000 or 2000 corrosive sublimate. The substance is a reddish yellow powder, readily soluble in water.

RIEDEL and LANGENBUCH have used its solutions in more than 100 various operations, with good results. Ammonia water removes the yellowish stain it imparts to the integument. In solution, 1 to 1200 to 1 to 1500, a teaspoonful, taken every two hours, will rapidly relieve dyspepsia attended by the presence of bacteria. In solution, 1 to 1200, it is a good injection in gonorrhœa.—*Berliner klinische Wochenschrift*, No. 40, 1887.

The Action of some Substances upon the Secretion of Microbes.—At a recent meeting of the Society of Biology of France, CHARRIN and ROGER reported that certain substances, notably mercuric chloride, prevented the formation of the customary colored secretions of various microbes. A strength of seventy-five grains to the quart was sufficient to produce this effect, which was not chemical, but a modification in the functions of the microbes.—*Le Progrès Médicale*, November 12, 1887.

Antipyrin in Diabetes.—GÖNNER reports in the *Correspondenz-Blatt für Schweizer Aerzte*, No. 19, 1887, the case of a man, aged sixty, who had suffered from diabetes for six years; in whose urine as high as six per cent. of sugar had been found. After antifebrin to the extent of 135 grains had been given, Trommer's test failed to discover sugar. The drug was then continued for ten days, 45 grains daily, and a permanent improvement followed in ten days time.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JANUARY 7, 1888.

ADULTERATION OF FOOD AND DRUGS.

NEARLY a year ago there was a meeting in Washington of delegates from various societies, boards of trade, etc., in accordance with a request issued by the American Society for the Prevention of Adulteration of Food, etc., of Philadelphia. After the Convention had perfected its organization it proceeded to discuss the form of a bill to prevent the adulteration of food and drugs, which bill it would recommend to Congress for enactment. The form of bill which was finally agreed upon is substantially the same as that recommended several years ago by a committee of experts appointed by the National Board of Trade, of which committee, Dr. J. S. Billings was chairman. Its essential features are: *First.* Prohibition of adulterations which are dangerous to health. *Second.* Regulation of adulterations which are not dangerous to health, so that consumers may know what they are buying. *Third.* That its provisions shall correspond to those most approved in State Laws relating to this subject, and, especially, to the laws of Massachusetts, New York, and New Jersey; and, *fourth*, that the jurisdiction of the United States in this matter is to be confined to the District of Columbia, the territories, and the forts, navy yards, etc., under the exclusive jurisdiction of the Federal Government, and to inter-state and foreign commerce.

This last principle is one that must be carefully kept in mind, for the subject of adulteration of food and drugs is one that comes under the "police power" which, by the Constitution, is reserved to the several States. The individual States cannot, however, fully regulate this matter, for it is practically impossible for any State to prevent the importation of adulterated articles. This, however, is precisely what the United States can do, by virtue of its power to regulate commerce, and thus if the action of the several States and of the United States is harmonious, and based on the same principles, each can powerfully aid the other.

So far as food is concerned the evidence is quite sufficient, that while many articles are adulterated, few of the adulterations are dangerous to health. There are frauds which should be prevented in the interests of the public as well as in those of honest manufacturers, and the provisions of the bill as regards foods have been framed from this point of view. The case is different as regards drugs and medicines, for all adulterations of these must be regarded as dangerous to health or life. If the drug has not the powers and properties which it should have in the usual dose the physician will not obtain the effect which he desires, and which he has a right to expect. A remedy of uncertain strength, which must be experimented with to learn how much of it is required to produce sleep, or purgation, or action of the kidneys, or skin, is one which the physician would never use if he could help it; but, unfortunately, he often cannot help it.

No class of the community would more gladly welcome effective legislation preventive of adulteration of food and drugs than would medical men. We are, therefore, glad to see that the Committee on legislation, appointed at the meeting above referred to, has issued a call for the meeting of another convention at Washington, January 19, 1888. and it is proposed to urge strongly upon Congress the importance of speedy action.

One of the chief reasons why Congress failed to act when the matter was brought before it several years ago was, because of the action of certain bureaus and departments which wanted to control the matter. No doubt some of this feeling still exists, and this must be recognized as an obstacle to be overcome, but the feeling is, perhaps, now less intense than it was, at all events we hope so.

If we are to have any form of National Health organization this matter would properly come under its supervision, otherwise a special bureau for the purpose should be created. The United States is

now the only civilized country which does not regulate the subject of adulteration of food and drugs, by law, and it is certainly time that Congress and the States should take action in the direction urged by the conventions to which we have referred.

THE ETIOLOGY OF CANCER.

There have been of late several attempts made to isolate microörganisms in cancer and sarcoma, but without success. About two weeks ago, the news was cabled that a physician in Berlin had solved the problem, and in our exchanges of December 1st and 5th we have the full report of Scheurlen's observations, and the discussion thereon at the Verein für innere Medicin.

Cultures were made, with the usual precautions, from ten mammary cancers, the medium employed being ascitic or hydrocele fluid sterilized for five days. Usually on the third day a growth, in the form of a colorless film, was seen on the surface of the serum, which became in time of a yellow-brown color. The cultures contained a short bacillus, 1.5μ to 2.5μ in length, which stained readily with the ordinary reagents, and showed spores. They could not be detected in the sections when stained, but in the fresh cancer juice, to the practised eye, they were readily recognizable. Six bitches were inoculated by injecting material from the cultures directly into the hinder breast gland, with the result of the formation, in about fourteen days, of a circumscribed tumor the size of a walnut. Two of the dogs were killed, one on the 28th, the other on the 30th day after inoculation, and each showed a small, solid growth in the fatty tissue of the gland, composed of epithelioid cells, in which could be seen the glistening spores of the bacilli.

In the discussion which followed, Guttmann expressed himself as satisfied that this was really the cancer bacillus, while A. Fränkel thought it more probable that the form described was not related etiologically to the disease, but represented a secondary invasion of the growth from the outside. In the same number of the *Deutsche medicinische Wochenschrift*, No. 48, Schill, of Dresden, states that he has found in cancerous and sarcomatous tissues rod-shaped organisms which grow actively on gelatine and form a rich mycelium. The description does not tally with that given by Scheurlen. Some time ago Freire also announced the discovery of a bacillus in connection with malignant growths.

In this connection we may refer to the results of an investigation by Ballance and Shattock, published in the *British Medical Journal* of October 29th, to determine whether malignant new growths which have so many and close analogies to the infective granulomata have a micro-parasitic pathology. Cultures were made from twenty-two cancers, the greater number of which remained sterile, and when a growth did occur the organisms were the same as those described and figured by various observers as occurring in the healthy tissues. With this disagreement we shall require additional observations before a final settlement of the question is reached. So many fruitless attempts have been made to inoculate cancer that it seems very remarkable to hear of definite tumors produced by the injection of the cultures. The question hinges on the precise nature and structure of these artificial growths; if really identical with the original tumors and containing similar organisms, the relationship will be as clear as in the case of Koch's bacillus and tubercle; but we must have more definite evidence than has been presented by any of the above named workers.

THE NEW YORK QUARANTINE STATION.

The "Alesia" arrived at quarantine in New York harbor on the 23d of last September. The press spread the news throughout the country the next day, but, because of general confidence in the thoroughness and efficiency of the establishment and administration of the quarantine at that port, no great alarm was occasioned thereby. On the 26th and 27th of that month the stricken immigrants were visited at their place of detention by the recent United States Cholera Commissioner for the purpose of ascertaining the presence or absence of the cholera bacillus of Koch in their dejecta.

At a meeting of the College of Physicians of Philadelphia, Oct. 5th, Dr. Shakespeare was called upon for a verbal account of his visit to the New York Quarantine Station. After relating the object of his visit and the finding of the comma-bacillus in the stools of the cholera patients, the general state of affairs which casually met his eye was referred to. The reference was so disquieting that the College immediately appointed a committee "to consider the present danger of the importation of cholera into this country, and to secure concerted action among the medical societies of the land in urging upon the State and National authorities the adoption of a uniform and efficient system of quarantine for all exposed ports." This Committee visited the

quarantine establishment at New York, Oct. 8th, and, subsequently, that at Philadelphia and at Baltimore, and on Oct. 28th they presented a report (see THE MEDICAL NEWS, Extra Issue, Oct. 29, 1887). After the dangerous state of affairs they discovered became known, an independent investigation was conducted by Dr. John C. Peters, on behalf of the Medical Society of the County of New York, and on October 26th he made a preliminary report to that body.

Under date of December 31, 1887, the Mayor of New York addressed a letter to the Governor, in which he states that the report of the Philadelphia Committee "was so unfavorable that I deemed it to be my duty to ask the Board of Health of this city to prosecute this investigation, and to invite a Committee of the New York Academy of Medicine to make a thorough examination of the quarantine establishment." The committee last referred to consisted of Drs. C. R. Agnew, E. G. Janeway, Stephen Smith, A. Jacobi, T. Mitchell Prudden, Herman M. Biggs, and Richard H. Derby. They began the investigation on the 19th of December, and their report with accompanying documents was transmitted to Albany with the letter of the Mayor, who in his comments thereon, says: "It discloses a condition of affairs which calls for immediate action of the Legislature. It is evident that neither the city nor the State, nor any portion of the Union is free from the dangers of the spread of contagious diseases, unless the quarantine establishment at this port under the control of the State authorities is at once reformed and reconstructed. The danger of delay is too imminent to admit of any postponement whatever." Mayor Hewitt has requested the Governor to transmit this report to the Legislature, and recommend such action as will secure adequate provision against the dangers of contagious diseases which will be liable to break out as soon as the warm weather approaches.

The report of Dr. Peters, that of the New York State Board of Health to the Governor, and that of the Committee of the New York Academy of Medicine, entirely agree with that of the College of Physicians of Philadelphia. Assuredly, no further testimony should be required to convince even those who have been most inclined to trust to our antiquated and, for the most part, dilapidated quarantine defences, that the country is practically without defence against diseases imported by sea.

The Committee of the New York Academy of Medicine admit that "every citizen of the United States has a personal interest in the condition of New York quarantine." The same admission must be made by every well-informed and unprejudiced mind with regard to every port in this country through which immigrants enter, or wherein infected persons or things arrive.

Why, then, should the direction, expense, and responsibility of a system of common defence against the inroads of foreign diseases, any more than against the invasions of foreign foes, be assumed and borne by those municipalities or States which happen to have a maritime location? Why should the vast majority, who are situated inland, be allowed to shift their responsibilities and obligations, or be denied a voice in the direction of affairs which so greatly concern them? The protection of the public health by maritime quarantine is a matter which interests not merely a narrow belt of seacoast; it seriously concerns the whole of the vast territory between our shores.

Mayor Hewitt has indeed done well. He merits the recognition of all earnest sanitarians, and deserves the thanks and support of his fellow citizens. Until we obtain a thoroughly organized National quarantine, by all means perfect the local establishments which already exist.

But we have again and again pointed out wherein it is impossible even for the best quarantine under local support and control to protect the general welfare to the extent that we have a right to demand. And the reports we have referred to and the Address of the Committee of the College of Physicians strongly fortify our position.

Efforts at reform of local and independent quarantines cannot radically cure evils which are universal. The only remedy is National support and National control of quarantine.

A NEW OPERATION FOR CARCINOMA OF THE STOMACH.

DISSATISFACTION with the published results of gastroenterostomy and Loreta's operation for carcinoma of the stomach in which the disease has extended to the surrounding parts, and thereby excluded excision, has induced BERNAYS, of St. Louis, to resort to free scraping or curetting of the mass when it projects so much into the stomach as to give rise to symptoms of pyloric obstruction.

The operation, which is described in the *Annals of Surgery* for December, 1887, consists in performing gastrostomy, and afterward removing the

growth with the fingers, spoons, and other suitable instruments. The wall of the stomach having been carefully united to that of the belly, the viscus is opened by an incision an inch and a half long, the lips of which are then firmly attached to the lips of the skin incision by many points of silk suture. The stomach having been washed out with warm water, the mass is torn and scraped away, when a current of iced carbolized water is turned into the stomach, through which it is induced to contract and, thereby, arrest the bleeding.

In the first case in which this procedure was resorted to, there was complete relief from the distressing symptoms, and the man did well for three months and a half, when the operation was repeated, with the result of again inducing comfort. In the second case, the result was equally gratifying, and the woman had gained twelve pounds in three months.

As a means of prolonging life and affording relief from the terrible symptoms of obstruction, the operation of Bernays will, we think, commend itself to the practical surgeon. It occupies the same position in regard to carcinoma of the stomach as does free curetting to carcinoma of the uterus and rectum, in the latter of which more particularly it has rendered excellent service.

THE TREATMENT OF DIPHTHERIA BY PERCHLORIDE OF IRON AND MILK.

IN the *Gazette Hebdomadaire* of November 4, 1887, NEKKACH recommends this treatment quite strongly, and, although it is by no means entirely new, it is, perhaps, worthy of notice. By this method he obtained seventeen recoveries out of twenty-two cases of diphtheria involving the larynx and pharynx.

The treatment consists in the administration of from twenty to thirty drops of the liquid perchloride of iron in a glass of pure cold water; or, better still, the patient is to take a large wooden spoonful of this water and iron mixture every few minutes, day and night. Immediately after the ingestion of the drug, the child is to take a large spoonful of cold milk, not boiled or sweetened. Cataplasms of flaxseed meal are also applied to the neck. In some instances the drug is applied directly to the part affected.

The objects attained are stated to be the prevention of further exudate, the production of a desirable astringent contraction of the tissues, and a tonic influence on the entire body.

Nekkach believes that by this means a certain curative effect is produced, that asphyxia is prevented, and that the epidemic tendency is actually decreased. The latter is, of course, exceedingly unlikely, except by a very indirect action.

THE HENDON COW DISEASE AND SCARLET FEVER.

VERY great interest was excited in England last year by an outbreak of scarlet fever in Marleybone, which, it was thought by DR. KLEIN and others, could be directly traced to a disease in the cows of a certain dairy at Hendon. Investigation showed that there was a specific, contagious, and infectious disease which could be communicated to healthy cows, and also by inoculation to man. It was believed to be distinct from cowpox, and Dr. Klein's experiments led him to conclude that it closely resembled scarlatina, and that there was a real danger of infection when the milk of diseased animals was used as food. We have already referred to this at length in THE NEWS of July 9, 1887.

Serious doubts existed in the minds of many as to the correctness of Dr. Klein's conclusions, and the Agricultural Department of the Privy Council commissioned Professor Crookshank to investigate the subject, and his report was read at a special meeting of the Pathological Society of London, and appears in the *British Medical Journal* of December 17th. He has studied two outbreaks identical in character with the Hendon disease, and has repeated Dr. Klein's experiments, but has reached the important conclusion that the affection is cowpox, and has nothing whatever to do with the propagation of scarlet fever. Very fortunately he was able to obtain a case of recent inoculation in one of the cow men, which proved to be a typical pox, and the lymph taken from it produced in calves characteristic vaccinia. There were no cases of scarlet fever on the farms or in the district to which the milk of the infected herd was distributed.

Whether or not the micrococcus which was described by Klein, and also found by Crookshank, represents the specific organism of vaccinia must be determined by subsequent investigations; and meanwhile the Agricultural Department of the Privy Council and Dr. Crookshank are to be congratulated on making out what was apparently a most obscure bovine disease.

IN New York City, on December 29, the Sloane Maternity and Vanderbilt Clinic were dedicated, and

made serviceable to the cause of medical teaching, at the College of Physicians and Surgeons. The medical address by Dr. T. Gaillard Thomas was an eloquent oration. Prof. Dalton and the Rev. Dr. John Hall also participated in the ceremony. An endowment has been promised whereby the beds will be free perpetually at the Maternity. Dr. James W. Markoe has been appointed house physician.

THE New York County Medical Society having been importuned to make an example of one of the "faith-healers," the counsel of the Society, Mr. Purrington, explains that the existing statutes do not aim at the punishment of this kind of imposture, when there is not a positive employment of medicine, or operation of surgery. The faithists have been brought into prominence lately by having a patient commit suicide at one of their "homes," and by the loss by death of a wealthy patient, whose case got into the "papers," whom friends believed might have been cured by prompt medical attendance.

DR. GEORGE D. HERSEY, of Providence, has been appointed visiting surgeon to the Rhode Island Hospital in place of Dr. Edward T. Caswell, deceased.

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, December 14, 1887.

THE PRESIDENT, J. SOLIS-COHEN, M.D., IN THE CHAIR.

DR. J. H. MUSSER, M.D., read a paper on

THE MORBID ANATOMY OF PERI-CÆCAL INFLAMMATION.

Much confusion, he said, appears to exist in regard to the nomenclature of the inflammatory affections of the region we are about to consider. It may, therefore, be well to define the various terms. By typhlitis we understand inflammation of the cæcum; by peri-typhlitis, inflammation of the peritoneum covering the cæcum; by para-typhlitis, inflammation of the connective tissue behind the cæcum. The term typhlitis is often used to include inflammation both of the cæcum and of the appendix. The term appendicitis is used for inflammation of the appendix, appendicular peritonitis for typhlitis of the appendix and its serous covering, and para-typhlitis for inflammation of the connective tissue around the appendix, or peri-cæcal inflammation.

Typhlitis has been considered by systematic writers to be a frequent affection, and yet it is difficult for pathologists to find records of post-mortems in which this condition has been found. It is true that some writers, especially the Germans, have described cases, particularly of stercoral typhlitis, in which inflammation and ulceration of the mucous membrane of the cæcum, by pressure from fecal impaction, was present. Most of us will, however, agree with Fagge that typhlitis is a good general expression used for all varieties of inflammation occurring in the right iliac fossa, but that in the majority of cases the correct term should be appendicitis. Wilkes and Fagge consider that the difference in degree of the inflammation alone accounts for the difference in the symptoms, and that the largest number of cases are due primarily to inflammation of the appendix. Perforation of the cæcum is most rare, and Fitz, in a most extensive research, was able to find but three cases, and in these instances, due to foreign bodies.

Inflammation of the appendix occurs both of the simple catarrhal and of the ulcerative type. Catarrhal inflammation with succeeding ulceration, local peritonitis, and, finally, perforation, also occurs; and the following conditions are generally found after death. In the first place, on section of the abdominal walls there is found, especially in the right iliac region, an œdematous state of the tissues; not only may there be serous œdema, but there may also be infiltration of pus, due to the burrowing from the primary abscess. The peritoneum, if involved, will exhibit an intense degree of inflammation with the characteristic injection, sometimes general, sometimes limited, and more particularly to the right iliac fossa and the pelvis. Serum will be found in the peritoneal cavity, and in some instances pus; blood is occasionally found. In the more severe forms, especially, large flakes of lymph cover the intestines, the parietal peritoneum, and the abdominal organs. The intestines are also more or less adherent to each other, depending upon the duration and the degree of the inflammation. The location of the abscess, for it is usually circumscribed, depends upon the position of the cæcum. There are three positions in which it is most frequently found—either in the right iliac fossa just above Poupart's ligament, or behind the cæcum, or in the pelvis. The size of the abscess varies, sometimes containing only two or three ounces of pus, and in other instances as much as a pint or more has been removed. The walls of the abscess differ according to its position. The appendix is always found in the abscess, and has undergone changes varying in degree with the duration and severity of the inflammation. Inflammation and ulceration of the mucous membrane, serous or purulent infiltration of the walls, with perforative ulceration and encysted or localized peritonitis, are discovered. In some instances a portion has sloughed entirely off and cannot be found, having undergone dissolution; in others it is found as a soft mass of necrosed tissue. The perforation varies in size; sometimes it completely surrounds the appendix, or even severs it in two, or it is sufficiently large to admit a probe only, while even in other instances it can scarcely be detected. Sometimes two or more perforations are found, and frequently they are covered by recent lymph. The canal of the appendix is very often dilated. We usually find in the canal, near the cæcum, a foreign body; it may, however, be found in the abscess. There is one point of importance in reference to the surgery of this region, and that is, that the perforation usually occurs within one and one-half or two inches of the colon. Whatever may be the length of the appendix, the perforation is, as a rule, found at the point just indicated.

There are, of course, many cases which do not terminate

fatally. Under such circumstances resolution takes place, or the abscess becomes encysted or ruptures into some neighboring organ. The abscess may discharge through the abdominal wall, through the scrotum, into the hip-joint, through the loin or the perineum, or in other directions. Sometimes the pus burrows upward, even as high as and into the pleural cavity. The bladder is a favorite seat for the rupture of such abscesses.

That cure may take place in cases of perforation of the vermiform appendix, was distinctly shown by a specimen in the museum of the Pennsylvania Hospital. And while it may appear to be a refinement of terms to differentiate between typhlitis and appendicitis, it is almost necessary in order that a correct and well-defined appreciation of the pathology be determined, so that early and proper treatment may be instituted. Unless such a refinement be made, cases of this kind will be frequently treated as simple typhlitis, whereas in ninety per cent., or perhaps a larger proportion, they are cases of inflammation of the appendix.

Dr. William Pepper made the following remarks on the

DIAGNOSIS OF PERI-CÆCAL INFLAMMATION.

The appendix presents evidences of disease in a very large number of indifferent autopsies. He remembered the report of a series of three hundred autopsies, in which there were signs of disease of the appendix in thirty-three per cent., although in none of these was there a history of typhlitis. We have this little organ, singularly useless physiologically so far as we know, placed in a singularly unfavorable position anatomically, very liable to become impacted, so formed that escape of its contents is very difficult, and very prone to become diseased. We must recognize the fact that the appendix is often diseased when we have no reason to suspect such a condition. He cannot agree, however, that the cæcum also is not often the seat of disease. He had collected a number of instances of independent cæcal disease, where the cæcum alone presented lesions, sometimes going on to chronic inflammation, ulceration, and perforation. The real condition of things seems to be this. In the first place, there are many cases of mild appendicitis which cannot be recognized during life; in the second place, there are a considerable number of cases of typhlitis where the symptoms are chiefly due to inflammation of the walls of the cæcum and of the peri-cæcal connective tissue, which end in recovery. It is impossible in these cases to determine what proportion has been due to appendicitis. Finally, there are also a good many cases of severe appendicitis resulting in ulceration and perforation, with the formation of circumscribed abscess or of general peritonitis. If we could accept the view that perforation of the appendix, leading to peri-typhlitis or para-typhlitis often resulted in recovery by resolution, it would be a matter of comparative indifference where the lesion was chiefly situated; but do clinical experience and anatomical records justify the view, that perforation of the appendix, followed by peri- and para-typhlitis, often ends in resolution? It is true that he had found one specimen and that others have been placed on record where perforation of the appendix has not been followed by grave results, but do these amount to anything comparable with the great mass of cases where lesions of the appendix have occurred with peritonitis and fatal result unless relieved by operation. We have to recognize that while in typhlitis, peri-typhlitis, and para-typhlitis, in all probability appendicitis always exists, yet it is often present in only a very mild degree, and can cause only a small portion of the symptoms. This conception seems necessary to a correct diagnosis of these lesions; and it is necessary in guiding our treatment.

There appear, then, to be two classes of cases. In one the affection is more limited to the walls of the cæcum and the peri-cæcal connective tissue, and the appendix is affected to a comparatively slight degree. We have no record as to the frequency of such cases. The record is not to be sought on the post-mortem table, for the large proportion of these cases, if properly treated from the beginning, end in resolution. He has the records of scores of such cases, the vast majority of which ended in resolution. These cases are marked by pain as the initial symptom, not excruciating in character, not associated with evidences of collapse, often accompanied by nausea and vomiting, and with elevation of temperature, which continues to rise until decided fever is present. With these symptoms there is excruciating tenderness in the right iliac fossa, a sense of fulness and induration, not rarely with dorsal decubitus and flexed thigh, with a constipated condition of the bowels, possibly preceded by one or two irritative movements during the first day, and with these there is considerable acceleration of the pulse. In proportion as the induration and swelling are early and marked, the chances are that the appendix is not seriously involved, but that the affection is chiefly one of inflammation of the walls of the cæcum and of the peri-cæcal connective tissue with exudation, and usually accompanied with considerable fecal impaction of the cæcum.

If absolute rest be insisted upon, if abstinence from food and absolute avoidance of interference with the state of the bowels be adhered to, if local depletion be employed, if counter-irritation followed by the application of the ice-bag, or warm fomentations be employed, and if the internal use of opium and mercury be begun early, the vast majority of such cases terminate in resolution and complete recovery, if the convalescent is properly treated—that is, if these restrictions be insisted upon until the sensibility of the part is entirely removed. The well-known tendency to the recurrence of typhlitis is largely dependent upon the management of the convalescence from the primary attack.

On the other hand, we know very well that such cases not rarely go on without resolving, that the induration extends, that the symptoms become aggravated and possibly are such as to indicate suppuration, and that at periods varying from seven to fifteen days pus formation occurs. Such cases demand operative interference, and are successfully treated by the Parker operation. The existence of pus can often be demonstrated by exploratory puncture with a fine aspirator needle.

There is a second class of cases of an entirely opposite character, with which we are all equally familiar. Here the patient may apparently have been in almost perfect health, for perforation of the appendix may occur without any previous symptoms of which the patient had complained. But in these cases there has been a catarrhal appendicitis; the fecal matter which is present in nearly every healthy appendix, is no longer able to circulate and escape, because the outlet is partially closed by the swelling of the mucous membrane; the pent-up secre-

tions and the irritating fecal matter excite more serious inflammation in the walls of the appendix; ulceration is established, and, finally, perforation occurs, and the symptoms of the attack begin. He has rarely seen a fatal case of disease of the appendix where there was not stenosis of its orifice, and he thinks that, to a large extent, it is this tendency to closure, and the accumulation of the secretions and of fecal matter, that causes the most serious type of inflammation and the occurrence of perforative appendicitis.

The first symptom in these cases is usually intense and excruciating pain, so severe at times as to cause collapse, occasionally so severe as to be followed by death in a few hours. Following this there is the rapid development of the signs of peritonitis. The pulse becomes frequent. There is marked tenderness, not in the iliac region only, but also toward the middle of the abdomen. The belly becomes distended, but there is no induration to be felt; there may even be no fulness in the right ileo-cæcal region. The appendix often lies under the cæcum, and he has frequently percussed these cases with great care without finding any evidence of dulness or of induration. After the occurrence of the initial pain, the fever may not rise very rapidly. There may be only moderate febrile reaction for one, two, or three days, associated with continued, moderate pain simulating an ordinary catarrhal attack with intestinal colic. For two or three days these cases may be viewed as not being seriously ill, so delusive may be the symptoms after the subsidence of the initial pain. In these cases there is absence of ileo-cæcal infiltration, or induration, or tumor, or prominence, or dulness on percussion. There is in these cases a less degree of vomiting than in the first class of cases mentioned. The vomiting is often rare, and only induced when the stomach is taxed. The bowels are quiet, but not so obstinately constipated and not so strongly resistant to the action of laxatives as in typhlitis, with more or less impaction of the cæcum. After a time, which varies with the intensity of the attack and the direction which the exuded matter has taken, there appear the symptoms of a rapidly spreading, general peritonitis. The belly becomes greatly distended and tender, the coils of intestine are outlined through the tightly stretched skin. The vomiting becomes frequent, the temperature rises, the pulse grows thready and rapid, and we have the familiar signs of general peritonitis. These cases end fatally, from exhaustion, in from five to ten days.

Here are two groups of cases which seem to differ not only in degree, but also to differ in the seat of their lesion and the character of that lesion. He cannot believe that in any great number of cases of the first group there is perforation of the appendix. Yet, unless perforation is present, we have seen that all the other lesions of the appendix may exist without the production of any symptoms. Therefore, he cannot attribute to ordinary appendicitis the symptoms of peri-cæcal inflammation which mark the first group of cases. These symptoms we must assign to the inflammation of the walls of the cæcum and of the peri-cæcal connective tissue in chief part.

It is, therefore, of momentous importance that we should be able to diagnose the sort of case that we have to deal with, and at the earliest moment. He should say, that in proportion as the tumor, prominence, induration, and dulness are marked, delay is safe, especially if rectal examination does not indicate any fulness on the right side of the roof of the pelvis. If this is present, it indicates an amount of exudation which will end in abscess, and is a strong indication for operation. If digital examination, pushed if necessary to the extent of the introduction of the whole hand, reveals no fulness in the roof of the pelvis, delay for several days is justifiable, and with such treatment as indicated, the symptoms will, in the majority of cases, subside; and, although the case is fraught with great anxiety, resolution will begin, the symptoms will become milder, and the patient recover, and under proper treatment the part will be restored to absolute health without relapse. Even if frequent relapses occur—and he had seen as many as fifteen or eighteen in the same individual—complete recovery may follow a protracted course of treatment with absolute rest, rigidly restricted diet, constant counter-irritation, and suitable alterative treatment internally.

Of course if, after waiting a few days, there is no evidence of the commencement of resolution; if the fever is sustained, particularly if it assume a hectic type, we know from experience that suppuration will not be long postponed. Exploratory puncture should be made, and operation should follow without delay.

The most important question to be considered is, What is the earliest moment at which we can establish the diagnosis? The initial symptoms give us some indication of the seat and the gravity of the attack. Typhlitis and peri-typhlitis soon offer demonstrable symptoms, but as the appendix is hidden under the intestine, the symptoms of perforated appendicitis are often obscure for two or three days. The most careful palpation may fail to show the slightest fulness. The patient may complain of pain over the cæcum, or over the hypogastrium. External examination does not aid us in the diagnosis. Are there any special features which will help us? He would again refer to the importance of the rectal examination. Early and oft-repeated rectal examination is the most important diagnostic means we possess in this class of affections. Often, on opening the body after death, there is no appearance of peritonitis in the exposed coils of intestine. There is no inflammatory process seen outside of the cæcum, and nothing is found until the cæcum is lifted up, when it is discovered that the inflammation is behind it, and extends downward to the pelvis. Sometimes, on removing a layer of lymph, a pelvis filled with pus is disclosed. In such cases, if rectal examination should give a sense of distention of the right side of the pelvic roof, might not a puncture be made with a curved exploring needle introduced through the rectum? In this way we might demonstrate the presence of pus, when it would not be possible to do so through the external abdominal wall.

In many of these cases there has seemed to be an unusual abundance of urine and an increased frequency of urination. He thinks that the former is associated with the absence of vomiting. In typhlitis and peri-typhlitis, there is often so much vomiting that very little liquid is absorbed, and the urine becomes concentrated. He had seen cases of perforation of the appendix, where the urine was voided at intervals of an hour or an hour and a half, the total amounting to a large quantity.

Again, it has seemed to him that in perforation the pain is more apt to extend to the middle line of the abdomen, and sometimes into the genitals, especially into the right testicle and spermatic cord.

The agony of pain which marks the initial lesion, the development of fever, the acceleration of the pulse, the distention of the abdomen, the pain referred to some point in the ileo-cæcal region, the comparative rarity of vomiting, the absence of induration and tumor, possibly, the ability to detect fulness or induration in the roof of the pelvis by rectal examination, the frequent micturition with a free supply of urine, the pain possibly radiating in the direction of the genitals, have been, in the majority of cases, the most marked symptoms.

Suppuration occurs in these cases very early, even earlier than in the other group of cases. In one case in which Dr. Keen operated for him as early as the close of the third day, perhaps the earliest operation on record, a pint of pus was found in the pelvis.

The point to which we should bend our exertions should be to determine the early diagnostic symptoms of these two varieties of cæcal inflammation, to see whether there is a constancy in the description that he has given of the first type of inflammation of the walls of the cæcum which, under proper treatment, offers a considerable hope of recovery. We should, in particular, strive to point out the indications for operation in the two classes of cases.

He would ask if general peritonitis may not be a positive indication for instant operation. It has been asserted that general peritonitis is not a contra-indication to laparotomy under other circumstances. If this is the case, the development of general peritonitis in a case of inflammation of the cæcal region would at once indicate operation, for after this develops death results under medical treatment.

Dr. Thomas G. Morton made the following remarks on

THE TREATMENT OF PERI-CÆCAL INFLAMMATION.

For practical purposes the treatment must be divided into two subdivisions, that of the pre-purulent, and that of the post-purulent stage.

The treatment of the pre-purulent, irritative, or simple inflammatory disorders of the cæcum and its surroundings, or appendix, should consist of rest in bed, restriction of diet to nourishing liquids, hot poultices or fomentations frequently replaced upon the parts, perhaps local depletion, and possibly the hypodermatic exhibition of morphia to control pain; whilst the bowels should be kept open and free from accumulations of gas and feces by the administration of salines and enemas—perhaps with the addition of turpentine to the latter.

Those disposed to cavil at the advice just given, he would ask: Shall we keep the bowels in liquid condition, and so best prepared to resist peritonitis, should it occur, whilst at the same time the mere draining of fluid from the intestines and surrounding parts would influence for the better the peri-cæcal inflammation? or shall we paralyze and congest, and inflate the bowels by the old-fashioned "splinting" treatment, and thus beckon on peritonitis?

Pain of intense character would often be as much an indication for operative relief as for morphia.

Prompt resolution should take place in cases which are not to go on to the stage of pus formation; and very long continuation of symptoms, or relapses, or recurrences, would be strong indications for surgical interference.

The presence of such tedious recovery, relapse, or recurrence would point to the probable presence of conditions exceedingly dangerous to the patient from liability to general peritonitis or perforation at any time; they further would point, as a rule, to the appendix as the source of irritation and danger. Indeed, in man, that worse than useless appendage must be regarded as the root of most evil in the region under consideration.

To illustrate this point by a single impressive instance, he quoted the case of a woman who, for a long time, had been having mild attacks of abdominal pain, located in the region of the cæcum, which had usually yielded with great promptitude to anodynes. During the course of the last attack of that nature, violent symptoms of perforation and general peritonitis came on. He did not see her until two days after this unfortunate accident; but, though she was then in a most desperate condition, he advised operation as her only chance, and forthwith performed abdominal section. The appendix was found perforated in two places, and violent general purulent peritonitis going on. She died a few hours afterward, but he felt better satisfied that the operation had been performed.

He then considered the treatment of the post-purulent stage.

In the great majority of instances, the presence of even a minute amount of pus so near to the peritoneum would be of vastly more risk to the patient than that of abdominal section for its relief. Hence, he would operate whenever the diagnosis of pus had been made—occasionally even without positive diagnosis.

Many other risks are to be taken rather than those of purulent peritonitis, for early interference will save most if not nearly all cases from this latter dread complication, while the danger of operation becomes slight compared to that of rampant abdominal inflammation.

Local or general peritonitis supervening in a person who has a history of cæcal trouble, or starting during a first attack, would more than justify operation.

At a later or even perhaps chronic stage of the disorder, all available diagnostic skill must be exerted when a peri-cæcal abscess may have pointed in an anomalous situation, and we must ever adhere to the modern surgical rule, always to attack pus at its source if possible. When the cæcum is normally placed, this is always feasible, if the disease be recognized.

Coming now to speak of actual operative measures, the patient, as a matter of course, must be got into the best possible condition, and surgically clean by the usual methods of attempting these ends. Asepsis should rigidly prevail throughout.

The aspirating needle must never be used, for if it does not find pus we cannot be sure that none is present, whilst its own dangers are not inconsiderable. In these cases it is a poor and especially unsafe diagnostic resource.

The abdominal incision should be lateral, *not* median. For if median the peritoneal cavity would often be needlessly opened, and the cæcum and appendix cannot well be reached or dealt with through it. But if lateral it can be made of less size, circumscribed abscesses will frequently be found before the peritoneum is reached, and at its base all necessary manipulations can be made upon the cæcum, appendix, and surrounding parts without opening the peritoneal cavity, whilst should the abscess or ulcer have reached that cavity the intestines, etc., can just as well be examined and cleansed through a lateral as a median incision.

The favored or lateral incision should begin at a point an inch above Poupart's ligament and to the outer side of the right linea semilunaris, be continued in a vertical direction upward about four inches, and carried down through the parietal muscles until pus, cæcum, or peritoneum encircling that organ be reached. Then the wound can be enlarged if necessary. If pus be found, wash its containing cavity clean, and get a clear view and careful examination of the cæcum and appendix. The latter is almost always the seat of trouble, and, perhaps, it would be well always to excise it whilst we have the chance, for any cæcal trouble will be likely in time to excite disorder of its appendage. Without a doubt it should be so treated if found inflamed, perforated, or harboring a foreign body. This can best be accomplished by ligating it as close as possible to its cæcal attachment and cutting it off. Cæcal perforations, if found, should be closed by Lembert sutures, whilst ulcers, which may be present but have not perforated, should by the same means be turned into the bowel lumen. If the general peritoneal cavity has not been involved, the abscess or cæcum or what not in view, should be gently curetted, washed out with a one to one thousand bichloride of mercury solution, a large glass or rubber drain introduced, and the abdominal wound closed around it with silk sutures, and a dressing superimposed.

If the peritoneum has become involved, and but a short time before the operation, the whole abdominal cavity must be most thoroughly washed out with hot (105° to 110°) distilled water, or one to ten thousand bichloride of mercury solution, and cleansed with sponges, and the foreign body, if that has been the source of trouble, searched for. Should peritonitis be found further advanced the intestines must be withdrawn, and all adhesions parted with the finger or knife during the process of cleansing and before they are returned to the peritoneal cavity. In the case of general peritonitis a glass drain must be carried to the bottom of the pelvis and kept in working order by means of absorbent cotton ropes acting by capillarity. If a second tube is not used for the superficial or peri-cæcal abscess cavity the drain going to the pelvis must have perforations as high in it as the level of the cæcum and any surrounding trouble.

If the inflammation should be caused by the presence of a foreign body in the cæcum itself or by impaction of feces, they must be either excised or urged by prudent force along the bowel. In their operative removal a simple incision, afterward united by Lembert sutures, would answer every purpose.

If portions of the cæcum have sloughed or become gangrenous and the breaches of continuity are too large to approximate with Lembert sutures without producing dangerous constriction of the gut, we will have to content ourselves with the formation of an artificial anus.

Post-operative treatment would consist in keeping the bowels in a fairly soluble condition, the tube clean, and in meeting threatening peritonitis by active purgation.

DR. W. W. KEEN said a word or two with reference to the diagnosis. He had seen many of these cases, and he has yet to see one in which a distinct tumor was present. As a rule, tumefaction will be found, but no tumor. Nor is any fluctuation found in these cases. In a case which he saw in consultation eight years ago, there had been extensive infiltration in the right iliac fossa, for three weeks; but there was absolutely no tumor and no fluctuation; yet, when the cavity was opened, a pint of pus was found. We should make up our minds positively, in reference to the surgical treatment of these cases, that we are not to wait for the formation of a distinct tumor or the presence of distinct fluctuation.

Another symptom, to which Dr. Pepper alluded, he has not found a constant one—and it is surprising that it is not—that is, the flexing of the right thigh. Not only may this be so, but all the other symptoms may be fading, and yet pus be present. In the *Medical and Surgical Reporter* for the early part of 1886, he reported a case in which he operated on the sixth day. The symptoms had followed the ingestion of a large quantity of grapes, the temperature reaching 102.8°. The fever and pain had nearly disappeared, and the other symptoms had ameliorated to such an extent that convalescence seemed almost established. Here the diagnosis and treatment hinged upon one measure, which he was rather surprised to hear Dr. Morton condemn—that is, the use of the aspirator. In these, and certain other cases, the use of the hypodermatic syringe for exploratory purposes is strongly to be commended. If it penetrates any normal structure, it will do no harm; and if it reaches pus, it gives a positive indication for operation.

The time at which pus forms is often extremely early. He had had two cases in which on the sixth day a large quantity of pus was found. Both of these cases made excellent recoveries. In the case seen with Dr. Pepper, pus was found as early as the close of the third day.

He was glad to hear Dr. Pepper refer so strongly to the importance of the rectal examination in these cases. The appendix often lies directly on the brim of the pelvis; if the perforation be near the cæcum, the pus will find its easiest outlet, in not a few cases, toward the cavity of the pelvis. It is, therefore, in the majority of cases, within easy reach of the finger; and, in an urgent case, if it cannot be reached by the finger, the introduction of the hand, provided it be a reasonably small one, may be practised.

Both Dr. Pepper and Dr. Morton have alluded to operation in these cases. As is well known the operation of Dr. Willard Parker consists of an incision not vertical, but parallel, to Poupart's ligament. This incision will do very well in the majority of cases, when the lesion is situated in the right iliac fossa proper. Either this or the vertical incision to which Dr. Morton alluded, may be selected. As we go further and do not find pus, the hypodermatic syringe may be used for purposes of further exploration. In the second class of cases alluded to by Dr. Pepper, where there is perforation of the appendix, where there is absence of induration in the right iliac fossa, and especially if there is general peritonitis, he should certainly favor median and not lateral laparotomy. The latter does not give so simple and bloodless an operation; nor does it give us so easy access to the cavity of the pelvis for exploration, for drainage, and for the surgical manipulations that may be necessary. In the case he operated on one year ago, for Dr. Pepper, he regretted that he did not do a median operation at once, instead of doing the lateral operation. The median operation gives every facility for operation on the viscera in the right iliac fossa, and especially it gives access to the appendix. Unless the indications for lateral operation be strong, he should favor the median incision.

He should hesitate to perform puncture of the rectum.

It would be far better to do a laparotomy, rather than in the dark, not knowing what the lesion was, simply to drain the cavity of the pelvis, as we would do by rectal puncture. We want to know what condition exists; we want to find out the exact facts. Exploratory operation is not only constantly done, but done, he might almost say, without any additional risk to the patient, and it gives us the means of dealing with whatever lesion we may find. If the appendix is perforated, we should ligate it and remove the diseased portion. If the cæcum should prove to be the seat of perforation, we should close the opening with the Lembert suture. If the perforation is too large for this, it will be necessary to follow the plan suggested by Dr. Morton, and make an artificial anus.

Dr. W. Hunt said that the suggestion has been made that treatment with salines should take the place of the opium treatment in these cases, especially after operation. This is a point on which more experience is needed before we can reach a decision. When we take into consideration the fact that several cases of perforation of the appendix have been known to get well under the opium treatment, as proved by post-mortems long after, and also the fact that the mortality after the adoption of that treatment years ago, fell, to a large extent, we should not hastily abandon it.

With reference to the operation of ligating and cutting off the appendix, it seemed to him that by this method it might possibly be found that only mucous surfaces had been brought into contact and adhesion not secured. It would be better after removing the diseased portion to close the stump by the Lembert suture.

Dr. Wm. Osler said that the important point in connection with perforative appendicitis is, that in the majority of cases the perforation occurs first with slight inflammation in the neighborhood, perhaps lasting a few weeks or months, without exciting any special symptoms; and the first symptoms to which the attention of the physician is called, and which are rapidly followed by peritonitis, are those of perforation not of the appendix, but of the appendiceal abscess. In five instances of peri-cæcal abscess which he had examined, in every one of them there was evidence that the abscess had lasted some time. That this is the case is evident from the fact that there are many instances—of which he had had three—in which there was no perforation into the peritoneum, and no peritonitis occurred, yet there were signs of septic fever. The perforation had led not to general peritonitis, but to inflammation of the portal branches and diffuse abscess of the liver. This is a point which has not been sufficiently recognized in dealing with these cases of perforation of the appendix.

With regard to cæcal disease, we have all seen the cases which have been described by Dr. Pepper. They result, in the majority of instances, from impaction; and the induration which we feel is in most cases fecal. It is important to distinguish between these cases and appendicitis, for the majority recover. We, however, learn from post-mortem examinations that a considerable number of cases of perforation of the appendix also get well—cases, too, in which there have been no special symptoms.

He had had three cases of peri-cæcal abscess from disease of the cæcum. Two were cases of round ulcer of the cæcum. In both the cæcum was the only part involved, the ulcer not being larger than a quarter of a dollar. In both instances the perforation was posterior and had excited suppuration in the tissues as high as the kidney. In one instance the abscess had been opened in the loin and had discharged very freely. In the third case the perforation was due to cancerous ulceration. There was in this case a large perforation just beyond the orifice of the ileum.

Dr. J. C. Wilson desired to call attention to a group of cases in which there is more or less extensive and general peritonitis, and this peritonitis may be due, as Dr. Osler has pointed out, either to rupture of a peri-cæcal abscess or to primary rupture of the appendix, with the escape of its contents into the peritoneal cavity. He believes that in this form we have to deal with two essentially different processes. In the first place, we have those cases in which we have rapidly developing peritonitis as the result of the escape of the contents of the appendix, or of a peri-cæcal abscess, and these cases demand the surgical interference which has been indicated. He believes that there is another class of these cases in which the peritoneal process results, not in purulent exudation finding its way down into the pelvis, but in plastic exudation from the beginning. Here we have the typical symptoms of general peritonitis without the formation of pus. These cases, he believes, not only terminate in recovery, but do better without than with surgical interference.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, December 23, 1887.

The President, James Perrigo, M.D., in the Chair.

Dr. G. Wesley Mills read a paper on

PHYSIOLOGICAL AND PATHOLOGICAL REVERSION.

He said the terms physiological and pathological reversion had not been used by Darwin or other writers on evolution. Physiological reversion is a return to a condition functionally similar, if not identical with, that existing in some lower form; pathological reversion is a like result from disease. The *embryo* is physiologically as well as morphologically allied to aquatic animals and lower forms generally. In *old age* there are many reversions to conditions existing in the infant or lower groups of animals.

In slow natural death there is a series of reversions to conditions present in lower groups, the individuals sinking lower and lower in the scale of life. The mammals become more and more cold-blooded animals. In hypnotism, somnambulism, hibernation, and natural sleep there is most pronounced physiological reversion. In certain cases of disease (hysteria, etc.) the *respiratory* function of the alimentary canal, retained to a certain degree, is exaggerated, so that there is a reversion to a condition in lower forms, as the fish and turtle (pharyngeal respiration).

In the *renal* system, when the urine secreted is of a high specific gravity, as in fever, and in instances in which there is excess of uric acid, there is reversion in the one case to a condition found in lower animals, in the other to lower groups of vertebrates, as birds and serpents.

There may be in man a reversion in the *digestive* system to a condition allied to the regurgitation of food in birds or the ruminants.

In anæmia, leukæmia, chlorosis with defective development of the vascular mechanism, and cyanosis, there is pronounced reversion, either to the functional condition of lower vertebrates, or of invertebrates.

The same applies to those forms of cardiac disease involving regurgitations and imperfectly aërated blood.

In diseases of the *nervous* system reversion is especially well seen. An animal poisoned by curare is reduced to the condition of a cold-blooded animal, so far as heat production is concerned. Animals, from which considerable portions of the cerebral lobes have been removed, are more machine-like, and thus resemble creatures much lower in the scale, as is proved by Goltz's experiments. In lesions of the cerebrum the more voluntary muscles lose power first, and the more extensive the lesion the lower in the scale the animal sinks; man leads a mere vegetative existence.

In all the above cases, and many more reversions which can be produced experimentally on animals, the question always arises, Why is the change of the peculiar nature it proves to be?

Unless we take into account the derivation of mammals, including man, from lower forms—a derivation which is physiological as well as morphological—it does not seem possible to interpret the true significance of the facts.

DR. SHEPHERD said that for many years he had been interested in the subject of evolution, but the point of view from which he had studied it had been entirely morphological. He believed that the physiological aspect of the subject had not been much regarded, and that, therefore, he considered the points brought out by the reader of the paper to be, to a great extent, new; they were at least new to him, and he thought that Dr. Mills had opened up a wide field for investigation. He himself was a thorough believer in evolution, for how otherwise could he explain the existence in man of rudimentary organs, anomalous and useless muscles, etc., which have their perfectly developed condition in animals lower in the scale, and in them fulfil a definite purpose.

He was aware that in the development of the embryo we saw the compressed history of the development of the race, but the statement made by the reader of the paper that in the death of the individual this history was read backward, was new to him.

DR. STEWART had listened with much interest to the paper, which in many of its features was entirely new. The reader had not, however, drawn attention to the fact that in persons dying of old age the death was through the bloodvessels; some one had said that death from old age was the evolution of dissolution.

DR. RUTTAN then read a paper entitled

SOME LABORATORY NOTES ON PAPOID DIGESTION.

It embodied the results of some experiments recently made by him on this interesting ferment. After giving a résumé of the work done by others, and calling attention to the contradictory nature of many of the published results, he first showed that papoid contained a proteolytic ferment, which was most active in neutral or faintly alkaline solution, its maximum activity being seen in an alkaline solution of a two per cent. sodium carbonate. A higher percentage of alkali retarded its action, while in an acid solution of three per cent. hydrochloric acid it seemed wholly devoid of peptonizing properties. He did not believe that papoid would do true digestive work in an acid medium. Comparing its proteolytic action with that of pepsin and pancreatin, he found that it was a more rapid proteolytic agent in neutral solutions than either.

In a series of experiments in which these three ferments were placed, each in conditions most favorable to its functional activity, he found that papoid was but little inferior to either in peptonizing power. He tried a number of experiments on diphtheritic membrane, and found that in a neutral solution, a five per cent. solution of papoid digested 8 grains of diphtheritic membrane in twenty-six hours, and 5 grains in twenty-four hours; in a parallel experiment in a neutral solution, it had only partially digested a similar quantity of membrane in thirty hours. In all the experiments the digestions were made with 15 grains of fibrin thoroughly washed and reduced to fine, dry powder. This was softened by boiling water after weighing and allowed to stand twenty-four hours before it was used for digestion. He thought that the discordant results obtained by many could be explained by the use of such substances as cooked meat, boiled white of egg, etc., as materials to be digested, as the amount of these substances digested would be very difficult to estimate accurately.

In concluding he said that while papoid would not do all that was claimed for it, it was still a very useful addition to the therapeutics of dyspepsia. It was probably, for the experiments made by him, not seriously injured by being kept in an acid medium for two to three hours; hence, although its action might be nil in the stomach, it would be capable of resuming its activity in leaving that viscus well mixed with the food. Its advantages in diphtheria as a local agent are threefold: first, it acts in a neutral solution better than any of the other ferments; secondly, it is not affected by the accumulation of the products of digestion (it acts best in very concentrated fluids); thirdly, it is antiseptic as well, and completely destroys the peculiar fetor of the disease.

NEWS ITEMS.

The Just Conclusion of a Malpractice Suit.—The suit of Mrs. Stogdale, against Dr. W. H. Baker, for malpractice in the removal of the ovaries, at the Boston Free Hospital for Women, in which $10,000 damages were claimed, has been decided in the physician's favor, after four trials. A remarkable and excellent feature of the trial was the action taken by the counsel for the defence, obliging the plaintiff to give bonds for costs, if the verdict was against her.

The courage and fortitude displayed by the defendant in this case, are worthy of imitation by others under like circumstances.

Leprosy in America.—*The Sanitary News* reports cases of leprosy as coming to the notice of the authorities at Savannah, and in a small town in Kansas.

A Suit for Typhoid Infection.—Suits at law having a sanitary bearing are becoming very common. The latest one is reported from Indianapolis. William Shiel has sued John Best for $1500 in damages. Shiel's family was prostrated with typhoid fever, and he charges that Best emptied slops and general filth into a cesspool so

close to his house that the disease was the result. Best claims that Shiel constructed a vault but a few inches deep, and that a heavy rain washed its contents into the cellar of Shiel's house, and that that was the source of the disease.—*Sanitary News*, December 24, 1887.

Family Hygiene during Infectious Disease.—*The Sanitary News* of December 23, 1887, gives some suggestions for the prevention of the spread of an infectious disease, taking it for granted that a case has developed in a family, and that it is desired to prevent its spread and not remove the patient from the house. They are formulated from a paper read by Francis Vacher, Health Officer of Birkenhead, England. The first requisite is to prepare a room in which the patient may be isolated. It should be cleared of all furniture which is not absolutely required, and the floor should be cleansed and left bare. The room should be regarded as a source of danger and should be cut off from the rest of the house by means of a sheet, or sheets, wrung out with a disinfectant solution and kept moist therewith, suspended outside each door, and reaching to the floor. Everything taken into that room should be regarded as infected, and nothing should be removed without disinfection. Towels, pocket-handkerchiefs, soiled linen, etc., used in the room, should be boiled in a disinfectant solution. The patient should be washed with a disinfectant solution and soap and water, and in scarlet fever the body should be anointed with oil. An open fire should be kept in the room, winter and summer, and if no ventilation is provided in the house construction, a window should always be left open a little. Dogs, cats, and other pets should be excluded from the room, as they carry infection readily. In case the patient should be so unfortunate as to die, the body should at once be swathed in disinfectant cloths, and should be sealed in a metal coffin before being removed from the room. When the room is no longer required by the patient it should be thoroughly disinfected. It should then be left open to air thoroughly for a week, all its contents should then be washed, and all suspected articles, such as toys, should be burned. With this treatment, an infected person should be taken good care of, and the case terminate without communicating the disease to others.

Successful Removal of a Pin Impacted in the Larynx for Two Years.—DR. LANGMAID, of Boston, reports, in the *New York Medical Journal* of December 24, 1887, the case of a woman from whose larynx he extracted a large pin, swallowed two years previously. Mackenzie's large laryngeal forceps was the only instrument sufficient to remove it from the ventricular band.

Bequests to Medical Charities.—By the will of the late Mrs. J. J. Astor, of New York City, $160,000 are bequeathed to charitable institutions, of which St. Luke's Hospital gets $25,000, and the Women's Hospital the same amount.

In Boston, the will of the late William Hilton provides that the Massachusetts General Hospital and the City Dispensary shall each receive $50,000.

Professor Eulenburg.—The death of this well-known hygienist occurred in Berlin, December 7, 1887, in his seventy-sixth year. Early in life he studied Swedish gymnastics in Stockholm, and subsequently introduced into Germany many procedures for mechanical and orthopædic treatment. He had recently presented $2500 to the Berlin Medical Society.

The Death of Leon Bassereau is announced, at Paris, aged seventy-seven years. He was a cousin of Madame Recamier, and a man of high accomplishments. His fame as a medical man rests upon his work as a syphilographer; he was the author of the "dual theory" of syphilis. He was a Chevalier of the Legion of Honor, and a member of various societies. His writings were on the Dual Theory of Syphilis, and on the Influence of Iodide of Potassium in Syphilis.

CORRIGENDUM.

ORIGINAL ARTICLES.

SELECTED CASES OF SARCOMA OF BONE AFFECTING THE LOWER EXTREMITIES.[1]

BY FREDERIC S. DENNIS, M.D.,

PROFESSOR OF PRINCIPLES AND PRACTICE OF SURGERY IN BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK CITY.

THIS subject is fraught with great interest on account of the meagre knowledge which we possess, and of great importance owing to the fact of the terrible mortality which attends the disease. Sarcoma of bone inevitably terminates in death, and its early recognition and its complete removal are subjects which are worthy the profound study of the surgeon. I believe that sarcoma, in the large majority of cases, is a disease more deadly in its nature than any other variety of malignant tumor. Its unprecedented rapidity of growth, its widespread metastases, its insidious development from unknown causes, its uncertainty of early diagnosis, its absolute certainty to kill, make this disease a subject of paramount importance.

The appalling impressions which I have received from a large clinical experience with this dreadful malady lead me to regard this neoplasm as one to which the thoughtful attention of the surgeon should be assiduously directed.

Entertaining these views, as I do, not from hearsay, nor from book-knowledge, nor from a narration of recorded cases by others, but from actual clinical experience with the disease, I know of no subject to which I could invite attention that concerns us more than this.

In studying the subject there have arisen a number of important questions which I shall introduce, with a view to elicit discussion upon these points. It is in this way, by accumulative investigation, and by comparison, that the surgical profession can acquire knowledge upon such diseases. The malignancy, the etiology, the clinical history, the prognosis, the diagnosis, and the treatment, besides other important subjects in regard to tumors, can only be understood by an exhaustive study of a number of individual cases. The consideration of a typical case of sarcoma of bone, for example, affords no reliable knowledge which could be applied to another case of sarcoma of bone. This variety of malignant tumor of bone has a wide range of difference, and it is only by comparison that we can arrive at any satisfactory knowledge.

Before taking up a study of individual cases, a few remarks upon the general subject of sarcoma in relation to its definition, its origin, its situation, its etiology and its classification seem pertinent.

The first question which naturally suggests itself is, What is sarcoma?

Sarcoma is a tumor; and a tumor, according to Virchow, is "a circumscribed new formation of tissue." All tumors are divided into three groups:

I. *Histoid tumors*, which are composed of some one of the many forms of connective tissue. They are derived from the middle blastodermic layer of the fœtus. Lipoma is a typical example.

II. *Organoid tumors*, which are composed of several of the normal tissues of the body, and these tissues stand in relation to each other as in the organ. They are derived from the middle blastodermic layer also, with some elements derived from the internal or external blastodermic layer of the fœtus. Adenoma is a typical example.

III. *Cellular tumors*, which are composed of tissues differing from the normal tissues of the human body in the extreme abundance of the cells. They are derived from any of the three blastodermic membranes of the fœtus. There are only three tumors belonging to this group, viz., carcinoma, sarcoma, and granuloma. It is thus evident that *sarcoma* is a tumor which is composed of tissue cells which normally belong to the human body, and that only extreme proliferation of normal connective-tissue cells is necessary to produce a sarcoma. It is, therefore, a growth of no foreign tissue, and the only difference between normal connective tissue and sarcoma lies in the extreme and rich abundance of the cells. The general impression that in malignant tumors there are new structural elements is incorrect, for cancer as well as sarcoma and granuloma, as also all other tumors, is simply the result of excess in growth of normal tissue, or else the presence of normal embryonal tissue in places where that tissue does not physiologically belong.

In the three germinal layers: 1st, the epiblast, from which skin develops; 2d, the mesoblast, from which distinct organs and systems of organs develop; 3d, the hypoblast, from which mucous membrane and glandular organs develop, there is found a key to a solution of the origin of these malignant and benignant growths. A careful study of the situation of tumors in the body demonstrates the fact that

[1] Read before the New York County Medical Association, Dec. 19, 1887.

tumors are found, as a rule, in parts of the body where in the fœtus the cell growth is complicated, as, for example, at the junction of the skin and mucous membrane. Here there is found a union of the tissues derived from the epiblast, the mesoblast, and the hypoblast. Cancer of the lip is a good illustration of this law. Tumors also develop at points where there is constant irritation or mechanical activity; an illustration of this law is found in malignant disease affecting the lips, the pylorus, the cæcum, the rectum, or the testicle when it remains in the inguinal canal. Tumors again develop in special organs which are the seat of physiological activity, as, for example, the breast, the uterus, the testicle, and the parotid.

From such observations a fair inference can be drawn as to the etiology of malignant and benignant growths. The composition of these growths has already been shown to be of no new structural elements, but of perfectly normal elements and cells of which the human body is composed, only those cells are found in places where they do not belong, and where there is great mechanical or physiological activity. Might not the mere transposition of the cells in the embryo from places where they normally belong to places where they are foreign, associated with the fact that just these places where tumors grow are precisely those places where there is a union of the different germinal layers in the embryo, explain the etiology of tumors? The question of traumatism in developing tumors can be reconciled with Cohnheim's theory of modern pathology; because it is traumatism, perhaps, more than any other agency that produces proliferation in cell growth. The traumatism in itself may not be capable of even producing a malignant tumor; but traumatism in places where a transposition of cells in the embryo has already occurred might act as a predisposing cause to the development of malignant tumors.

With reference to the subject of a special bacillus to explain the presence of a sarcoma, for example, little can be said at the present time. That such an hypothesis may be true is still *sub judice*, and until we are possessed of more reliable knowledge upon this subject, based upon experimental work, the question cannot be said to be settled. In the light of our present knowledge of the etiology of suppuration it is not at all unlikely that in the near future this theory may be proved. However this may be, the law of the transposition of cells, and their proliferation by traumatism would in no wise affect the present state of the subject.

These remarks seem pertinent in order to bring out clearly the place which sarcoma has among the group of tumors. The digression also serves to explain some points in reference to the relation of traumatism to malignant tumors. It is to sarcoma in particular that traumatism seems to act as an exciting cause, and in the cases reported I shall call attention to this fact in connection with some striking examples of sarcoma following rapidly upon traumatism.

Sarcoma has been classified by Virchow in a way that is generally accepted by surgeons and pathologists. It is the best classification in use and with but a slight modification I shall employ it upon the present occasion. Sarcoma may be divided: 1st, *according to the character of the cells:*

1. Spindle-cell sarcoma (like ordinary connective-tissue cells).
2. Round-cell sarcoma (similar in form to leucocytes).
3. Giant cell sarcoma (such as are seen in medulla of bone).
4. Mixed cell sarcoma (composed of some or all of the above variety of cells).

and 2d, *according to the character of the connective substance.*

1. Connective tissue.
2. Gelatinous tissue.
3. Fatty tissue.
4. Cartilaginous tissue.
5. Osseous tissue.

Hence a sarcoma is named according to the variety of connective tissue substance of which it is composed together with ordinary connective-tissue cells.

Thus, for example, if gelatinous tissue is connected with pure connective tissue cells a myxo-sarcoma is developed. I have a beautiful illustration of a myxo-sarcoma growing upon the leg of a patient upon whom I expect to operate. If fatty connective tissue is in combination with ordinary connective-tissue cells, a lipo-sarcoma is developed, of which also I have a typical specimen.

Occasionally a sarcoma is composed of many forms of connective-tissue substance, and it is then termed a mixed sarcoma. This form must not be mistaken for a mixed cell, which differs from a mixed sarcoma in the way already mentioned.

In discussing sarcoma limited to the long bones a very simple classification can be made upon a pathological basis, viz.:

I. Subperiosteal sarcoma.

II. Central sarcoma.

The *clinical history* of sarcoma is an interesting feature of the disease. It is the malignant disease of early childhood, and has been seen in an infant under one year. As a rule, it is a tumor which develops suddenly and which runs oftentimes a rapidly fatal course. In two cases only have I seen the tumor grow slowly. Sarcoma of bone is usually a nodular, painful, rapidly growing neoplasm which in the later stages begins to ulcerate. If it grows from the subperiosteal tissue it is found to affect the shaft of the bone; is not distinctly circumscribed, grows very rapidly, and is not associated with inflam-

matory processes. If the sarcoma grows from the centre of the bone it usually affects the extremities of the bones instead of the shaft; it is a distinctly circumscribed neoplasm instead of a diffuse swelling, and grows slowly, which is in marked contrast to the subperiosteal variety. The slow growth is due to the fact that absorption of bone must take place by pressure of the tumor. This pressure causes atrophy of bone, and this process is necessarily slow. The central sarcoma has an egg-shell crepitation in the later stages of the disease. This crepitation is due to the breaking of the attenuated and fragile shell of bone which has been pushed out by the growth from within, and is a pathognomonic symptom of central sarcoma.

The malignancy of sarcoma is manifested by its widespread metastases, by its complete annihilation of adjoining tissue, by pressure effects, and by hemorrhages due to ulceration, by its infiltration through bloodvessels in the majority of cases, and, finally, by its rapid strides toward a fatal termination unless interrupted by a radical operation.

The *diagnosis* of sarcoma in its early stages is often very difficult. The microscope only can decide in some cases. Time, which might afford definite information, cannot be utilized for the purpose of diagnosis. Procrastination in coming to a decision is too dangerous an agency to employ to settle such a momentous question. The use of the harpoon will throw intelligent light upon this doubtful and grave question, and settle beyond all peradventure the malignancy of the growth.

Great care should also be exercised in not making undue haste in coming to a conclusion as to the question of a growth being sarcomatous. I have had three cases sent to me for the purpose of amputation on account of sarcoma. Each of these three cases proved to be a chronic inflammation of bone, and each was completely cured without amputation.

One of these cases was of the thigh, the other two cases were of the tibia, and all three cases had consulted surgeons, who pronounced the neoplasms malignant and advised amputation.

The points of differential diagnosis between sarcoma of bone on the one hand, and chronic inflammation of bone on the other hand, are as follows:

SARCOMA OF BONE.	CHRONIC INFLAMMATION OF BONE.
1. Attacks extremities unless subperiosteal.	1. Attacks the shaft.
2. Forms soft swelling in comparison with sclerosis of bone.	2. Forms hard smooth bone.
3. Rapid in its course.	3. Slow in its course.
4. Distended veins over the surface of tumor.	4. No distended veins over surface as in sarcoma.
5. Does not invade joint.	5. Usually invades the neighboring joint.
6. Circumscribed areas of fluctuation over swelling where cysts filled with bloody serum are found.	6. There may be diffuse area of fluctuation; but pus is found instead of bloody serum.

Another very important differential diagnosis must be made between sarcoma and carcinoma.

SARCOMA.	CARCINOMA.
1. Origin of growth is from the mesoblast.	1. Origin of growth is from mesoblast and also from hypo- or epiblast.
2. Disseminates by bloodvessels.	2. Disseminates by the lymphatic channels.
3. Tumor may be enclosed in a capsule.	3. Tumor is never enclosed in a capsule.
4. Cachexia appears late in the history of the tumor.	4. Cachexia appears early in the history of the growth.
5. Disease of early life or middle life.	5. Disease late in life as a rule.
6. Not so painful a tumor as carcinoma, and may develop with little or no pain.	6. Sharp, lancinating pains as a rule.

The *prognosis* in sarcoma is as gloomy as can be imagined. It is a disease which destroys life rapidly, unless arrested by amputation. The prognosis may be modified as regards time by the situation and the particular cell variety of the sarcoma. In whatever way we look at the prognosis it is serious. On the other hand a radical amputation may rescue a patient's life even in the cases of the most malignant variety. I shall furnish examples of this fact in the list of the cases that I have operated upon within the past few years.

The *treatment* of sarcoma of the long bones is simple, because there is but one operation, and that is amputation. From an experience derived from a number of these cases of sarcoma of bone, and from opinions formed after careful study of the cases of others, I am more and more impressed with the fact that amputation is the only operation which should be contemplated. I refer to sarcomata of the long bones. The operation of exsection or enucleation, and an application of caustics are, in my humble judgment, productive of harm; because the disease is not as a rule radically removed by these methods, and oftentimes the tumor returns very rapidly, and the operation seemed only to add fuel to the fire.

I believe that in all cases of sarcoma of the long bones amputation should be decided upon at the earliest period possible, and the operation performed without delay. At the point of election I would suggest an amputation which would remove the entire bone affected, whether it is a subperiosteal or central sarcoma. This necessitates an amputation of the lower part of the thigh in case the tibia or fibula is the seat of the neoplasm. It necessitates an amputation of the hip-joint when the tumor is subpericsteal, and involves the shaft of the femur. In view of the great mortality of hip-joint amputation, a possible exception might be made in case of a central sarcoma of the condyle of the femur which was recognized early, and which was small in size. By amputation in the lower third of the femur in sarcoma of one of the bones of the legs, the popliteal glands are thus removed, and while this point would con-

cern us more if the disease were cancer. yet I have seen a case of sarcoma affecting those glands.

The remedy of amputation which is suggested. is a severe one; but the disease for which the amputation is performed is a uniformly fatal one if left to nature, and in view of the great malignancy of sarcoma, I believe the operation should be the most radical one consistent with a due regard for the life of the patient during the immediate performance of the operation. It must be remembered that the patient is suffering from a uniformly fatal disease, and the chances of escape from it are in proportion, within proper limits of course. to the distance at which the limb is removed from the seat of the malignant tumor.

In offering a succinct report of a few of my cases of sarcoma of the long bones of the lower extremities, I shall endeavor to dwell upon the particular features of each case, and then in conclusion deduct some inferences which the study of these cases collectively seems to warrant. In the data which I shall give in the final conclusion I shall avail myself only of those cases which I have had under treatment. At some future time I intend to tabulate my cases of sarcoma of the long bones of the upper extremities, and upon another to group the cases of sarcoma of the skull and pelvis. I have carefully prepared notes of upward of fifty cases of sarcoma. of which number thirteen belong to the lower extremities. It is to a study of this group that I shall now invite your attention. Only those where the diagnosis was confirmed by the microscope will be considered.

I have had a number of cases where the sarcoma has affected the lower extremities; but where the starting-point was not from the periosteum or bone. This separate group. which forms a collection of great interest, I shall not embrace in the present paper. These sarcomata grew from fascia and lymphatics, and from the intermuscular septa. and from pigmented moles, which I believe are dangerous to leave upon the body, because they may become the starting points for sarcomatous ulcers. I shall also exclude from the present group cases of sarcoma developed from a retained testicle in the inguinal canal. and shall refer only to sarcomata having their origin from bone or periosteum.

CASE I. *Subperiosteal sarcoma of femur: amputation at hip-joint; death.* (Examined by Dr. Biggs.)—J. T.. æt. thirty-six. admitted to St. Vincent's Hospital May. 1884. He was sent to me by Dr. W. H. Robb. of Amsterdam. N. Y. August. 1883. patient was thrown from the end of a railroad platform-car. his left leg being caught in an iron upright. by which he was held suspended until released by some bystanders. Dr. Robb saw him at once. and found a transverse fracture of the thigh just above the knee-joint. The fracture was dressed in the usual manner with long side-splints and the weight and pulley. At the expiration of one month Dr. Robb found no union of the bone, and applied a plaster-of-Paris bandage. At the end of a fortnight the plaster was cut down, and still no union of the fracture. At the time of this dressing there was noticed a change in the circulation about the seat of the fracture; and this was supposed by the attendants to be a good omen, because it indicated that nature was making an effort to throw out bony callus. Another plaster-of-Paris bandage was applied for a fortnight. and then this dressing was removed. There was now noticed at the seat of the fracture a decided increase in the size of the limb, and there was no attempt at union. The plaster was now discontinued. and a splint was made of leather to support the ununited fracture. The patient was sent to me. The diagnosis of malignant disease which was made by Dr. Robb was confirmed, and notwithstanding the fact of the nature of the tumor, the patient refused to have his thigh amputated. He remained several months in St. Vincent's Hospital, during which time there were periods when the tumor seemed less painful and diminished in size, especially after the bloody serum was withdrawn by the aspirator.

In July the patient not only gave his consent to an amputation, but desired it in view of the unmistakable diagnosis of malignant disease. The tumor now had become enormous in size, and the patient's strength was very much reduced by repeated secondary hemorrhages. The tumor was also ulcerating and the discharges very foul. The amputation was performed in a little less than one year from the time of the original injury. The operation was not successful, and the patient sank rapidly, and died in a few hours.

Remarks.—The interesting features connected with this case are. 1. The relation of traumatism to the development of sarcoma. 2. The fact of the development of sarcoma from a traumatism of bone resulting in a fracture, and that the seat of fracture was the starting-point of the disease. 3. The probable chances of success if the patient had consented to amputation as soon as the diagnosis was made positive. 4. The rapidity of the growth in a few months.

CASE II. *Subperiosteal mixed-cell sarcoma of femur; amputation at hip-joint; recovery.* (Examined by Dr. Grauer.)—W. R., æt. seventeen. admitted to Harlem Hospital May 19. 1887. Patient sent by Dr. Johnson, of Blairstown. N. J. In January, 1887. the patient felt a dull, aching pain in the left thigh, the pain increasing at night. Shortly after the onset of the pain. a swelling appeared, which rapidly increased in size. Three months later the patient consulted a physician. who aspirated the swelling. and drew off several ounces of bloody fluid. In May. 1887. about five months from the first appearance of the pain. and three months from the beginning of the swelling, he was sent to me. His condition at this time was very unfavorable. From a strong. healthy boy in a few months he became feeble. weak. and cachectic. In a few weeks he lost upward of forty-five pounds. The family history as regards hereditary influence is negative. The urine

was normal. The tumor measured twenty-nine inches in circumference. On May 26, 1887, five months from the date of the appearance of the first signs and symptoms of the tumor, I performed amputation at the hip-joint. The hemorrhage was controlled by a simple elastic band, as suggested by Lloyd, of Birmingham, and applied by Dr. Garmany. The patient rallied from the shock, and made a good recovery, debarring a secondary hemorrhage, which occurred on the twenty-ninth day following the operation. The hemorrhage came from the artery which accompanied the ligamentum teres, and this hemorrhage, it is interesting to note, was caused by sloughing of the ligamentum teres, which was not cut off close to the bottom of the acetabulum, but instead was cut off close to the head of the femur: as a result, the ligamentum teres sloughed, and the hemorrhage occurred.

It is a point worthy of attention to cut this ligament close to the femur, and thus avoid this accident. The simple band, as applied, completely controls all hemorrhage, except from the obturator artery, which cannot be compressed, owing to its passage through the obturator foramen. If this fact is known, the surgeon can at once seize this artery, and then all bleeding is completely arrested until the other vessels are ligated. The patient is now in Bellevue Hospital, and there is no evidence of any return of the disease.

Remarks.—The chief points of interest in this case are, 1, the rapidity of this growth. There were only five months intervening between the onset of the first symptoms and the time of the operation. 2, the simple and efficacious method of arresting the hemorrhage. 3, the gloomy outlook for the patient, though he recovered from the operation.

In thirty-six cases of subperiosteal sarcoma of the femur, reported by Butlin, there was a death-rate of twenty-five per cent. in operations for removal of the disease. Out of the thirty-six cases only one could be said to have been completely cured by the operation, and about this one case there seems to be a doubt as to whether it was not a central sarcoma. The period of three years is taken as the shortest possible time which must elapse before a patient can be said to be cured. The prognosis is, therefore, very serious—for there is not a single case recorded in this list of subperiosteal sarcomata of the femur that was cured. This is most certainly a startling fact in connection with a study of these cases.

CASE III. *Subperiosteal sarcoma of fibula (round-cell variety).* (Examined by Dr. Grauer.)—J. H., æt. four. Family history is negative. Patient received an injury to the fibula, February, 1881, and shortly after this injury a small swelling began, which grew rapidly, until at the end of six months the lump became very painful, and the patient was unable to walk. On May 8, 1882, I amputated the limb just above the knee-joint. The tumor was examined microscopically, and pronounced to be a round-celled sarcoma. The boy rapidly improved in his general condition, and has been perfectly healthy ever since the operation, with no evidence at any time of a return of the disease. It is now nearly five years since the amputation, and a long enough time has elapsed to make it certain that no return of the disease will ever occur.

Remarks.—This case is interesting from several points of view. 1. The relation between traumatism and the development of sarcoma is demonstrated in this case. 2. The slowness of the growth in subperiosteal sarcoma. 3. The complete recovery, with no return of the tumor, notwithstanding the fact that the microscopical examination revealed the presence of the most malignant variety of sarcoma. 4. The encouragement to operate in these desperate cases, though the prognosis seems absolutely fatal at the time.

CASE IV. *Subperiosteal sarcoma of tibia.*—T. M., æt. seventeen. Family history is negative. Patient previous to April, 1884, enjoyed excellent health. In April, 1884, he struck his knee against a coal car. The injury was apparently slight. A small lump was formed, which soon grew painful. Patient consulted Dr. R. H. Gibbons, of Pittston. He diagnosticated sarcoma, and advised removal of the limb. Patient would not at that time consent to any operation. He was sent by Dr. Gibbons to me in August, 1884, about five months from the date of the injury. I advised immediate amputation, to which proposition he dissented. Upon return to Pittston in the latter part of August, he allowed Dr. Gibbons to try to enucleate the tumor, but would not consent to an amputation. In about three weeks after the operation, the tumor returned, and grew very rapidly until November 16, 1884, when he requested his leg to be amputated. At this late date, patient had become too weak, and finally died December 4, 1884, without an amputation, about nine months from the time of the injury.

Remarks—A piece of this tumor was examined microscopically and pronounced to be a subperiosteal sarcoma involving the upper end of the tibia. The chief points of interest in this case are: 1. The sarcoma following directly upon receipt of traumatism. 2. The rapid course of the disease. 3. The consequences of refusal to an amputation in face of a positive diagnosis of malignant disease. 4. The rapid return after enucleation.

CASE V. *Subperiosteal sarcoma of tibia, mixed sarcoma, consisting of a variety of connective tissue substance.* (Examined by Dr. Biggs.)—Mrs. B., æt. nineteen, was admitted to Bellevue Hospital October 1, 1885. Patient has always enjoyed good health. Nine months previous to October, 1885, patient felt a sharp pain in left leg just above the ankle. The pain lasted but a few seconds and then disappeared. There were occasional shooting pains in the leg until three months later, when severe cramps occurred. The foot became slightly œdematous and the swelling involved the leg. Patient at

this time was six months pregnant, and the swelling and pain now disappeared until the child was born. Shortly after parturition the swelling and pain returned and the tumor grew very rapidly.

In September, 1885, the patient was sent to me by Dr. Anderton, who made the diagnosis of sarcoma of the tibia, in which I concurred, and at the same time advised immediate amputation. On October 3, 1885, about nine months from the time of the first appearances of pain and swelling I performed a supracondyloid amputation of the thigh. Patient rallied from the operation and the wound healed by primary intention.

On April 17, 1886, seven months after amputation of the thigh a tumor developed upon the lower jaw. I removed this tumor at St. Vincent's Hospital. The tumor was sarcoma and appeared three months previous.

In March 23, 1886, patient returned to St. Vincent's Hospital with a tumor situated upon the upper jaw. This appeared a few weeks previous and grew very rapidly after the operation upon the lower jaw. In May, 1886, the clavicle became involved and then the lungs, and on May 11th the patient died.

Remarks.—The points of interest in this case are: 1. The rapidity of the growth of the tumor, as well as the multiple return of it, in which the metastases occurred in the bones, but finally in the lungs, which were examined by Professor Janeway. 2. The absence of any return of the disease in those places where an operation was performed. 3. The temporary arrest of the growth for several months during the period of pregnancy, and its very rapid growth immediately after parturition. This same phenomenon I have seen in a case of sarcoma of the breast. The growth was arrested during pregnancy; but grew rapidly immediately after parturition. The pregnant state seems to hold in temporary abeyance the growth of malignant tumors; but after this condition is removed, the growth takes place with great rapidity. 4. The medico-legal controversy which grew out of the treatment of this case—I refer to this point on account of the importance of the subject.

After the amputation was performed, the husband of the patient began a suit for $20,000 against me for amputating the leg on the ground that the tumor could have been removed and the limb saved. Notwithstanding free permission from the patient, as well as from the husband, to do as I thought best in the operation after cutting first into the growth and thereby giving her the benefit of the doubt, I was confronted with this dilemma. It is needless to state that the suit was never brought to trial. The full, verbal permission to amputate and the microscopical evidences of sarcoma, and the rapid return after a few weeks were all questions of great importance from a medico-legal aspect. The husband made some serious threats of a violent nature; but the sudden return of the disease, and the great suffering of his wife induced him to come back for further advice. I consented to operate on the upper jaw and afterward to operate upon the lower jaw, at the urgent request of the husband, whom I compelled to make his application in writing with full permission to operate as I thought best.

There is so much ignorance among the less educated upon the nature of the malignancy of certain tumors, and so great a natural antipathy to amputation for the relief of these tumors, that a surgeon, in order to protect himself, should refuse to have anything to do with uneducated patients unless he has obtained their permission in writing. A surgeon cannot otherwise protect himself against the unprincipled lawyer who plays upon the feelings and sentiment of his clients with visions of a large sum of money for supposed malpractice.

Case VI. *Subperiosteal sarcoma of tibia.*—W. R., æt. forty, admitted May, 1886, to Bellevue Hospital. Patient's family history negative. Two years and a half previous to his admittance he noticed a lump or swelling upon the internal malleolus of the left leg. There was no history of injury. The growth of the tumor was slow, so slow that he was, during all of this time, able to wear a shoe so constructed as to fit the slowly changing shape of his foot, which had the appearance of an aggravated talipes valgus. The urine contained considerable albumen, and a few granular and hyaline casts. He had been addicted to a free use of stimulants for many years. Diagnosis of *sarcoma* of tibia was made by Professor Sayre as soon as he examined the patient, and he sent him to me for operation, as I was on duty at the hospital at the time. It was deemed best to amputate the leg for the relief of the sarcoma, although the condition of his kidneys was known at the time of this decision. I performed the circular amputation, and the stump at the first dressing appeared in excellent condition, save a little bichloride irritation. He developed delirium tremens, and, with the kidney complication and exhaustion, died in ten days following the operation. The microscopical examination confirmed Dr. Sayre's diagnosis of sarcoma.

Remarks.—The points of interest in this case are: 1. The slow growth of this subperiosteal sarcoma, and in this respect in marked contrast to the other subperiosteal sarcomata. 2. The absence of pain. 3. The cause of death which was due to delirium tremens and uræmia, and not directly to the operation. 4. The difficulty of diagnosis in the early stages.

I have now two cases where sarcomata are present, but where the growths have occupied two years in developing, and on which account both of these patients refuse to have any operation performed. These patients are still alive, and although the disease in each case is progressing slowly, and the diagnosis seemed at first obscure, these tumors, without doubt, will suddenly grow rapidly at no distant date. These two cases present very unusual phenomena in regard to the growth of sarcoma.

CASE VII. *Central sarcoma of tibia, mixed, containing many different varieties of connective tissue.* (Examined by Dr. Biggs.)—J. F., æt. nine. In April, 1887, was struck on the lower end of the leg. Previous to this he had always been well. Following the blow a small swelling appeared upon the front and lower part of the leg. The lump grew rapidly, and he began to walk upon his toes. Four months after the above-mentioned injury the patient was brought to me. The skin over the tumor was healthy, and the swelling was about the size of an egg. There was a suspicion of an abscess in the bone. The parents consented to an exploratory operation, but would not consent to an amputation in case the exploration revealed the presence of sarcoma. The tumor was scooped out and the wound for a short time did well. He was removed from the hospital September 28, 1887, and taken home.

In November, 1887, he was brought back to St. Vincent's Hospital. The tumor was now as large as an orange, and presented the cauliflower excrescence so characteristic of these malignant growths in the later stages. The mother now consented to amputation; but made the proviso that the amputation should be below the knee. Accordingly, I performed the amputation on November 31, 1887. The Esmarch bandage was applied; but it was employed above the tumor, as it should be in cases of malignant tumors. A sarcoma should never be compressed.

Remarks.—The chief points of interest are: 1. The relation of traumatism to the genesis of malignant tumors. 2. The rapidity of the growth for a central sarcoma. 3. The impropriety of any exploratory operation. 4. The necessity of an amputation as early as the disease is recognized. 5. The necessity of full permission to amputate in case an exploratory operation is deemed necessary for the purpose of a diagnosis. 6. The presence of egg-shell crepitation, indicating the central origin of the tumor in contradistinction to the subperiosteal variety. 7. The encouraging outlook for this boy in contrast with the boy who had a subperiosteal sarcoma of the thigh. In twenty-nine cases of central sarcoma of the leg reported by Butlin, there was a death-rate of nearly thirty per cent. in the operation for removal of the disease. Out of the twenty-nine cases one patient only could be said to have been completely cured, taking three years as the standard of time. This high rate of mortality in the operation itself is a most astonishing fact, and is only surpassed by one still more startling, that out of this original list of twenty-nine cases only one single case was reported as having been completely cured.

CASE VIII. *Myxo-sarcoma of tibia.* (Examined by Dr. Biggs.)—T. W. æt. thirty-nine, admitted to Bellevue Hospital October 22, 1887. Family history of no special importance. In September, 1887, patient was admitted to the medical ward of Bellevue Hospital on account of chills, pains in head, chest, and back, and a swelling upon the left leg at the seat of an old fracture. He also had purpura hemorrhagica over his legs, thighs, and abdomen. October 22, 1887, he had nearly complete suppression of urine with a large quantity of albumen and casts. His general condition was improved, and on Nov. 4, 1887, he was transferred to the third surgical division. I made a diagnosis of sarcoma, and this diagnosis was confirmed by Dr. Biggs, who found a myxoma in the fungoid growth, and the tumor had caused a pathological fracture. Patient was given special diet, and tonics, with a view to improving his general condition preparatory to an amputation. His appetite increased, there was only a small amount of albumen in his urine, and the prospects of a successful operation for the removal of his malignant tumor seemed encouraging. He was induced, however, to leave the hospital, to have caustics applied, and would not consent to an operation.

Remarks.—The points of interest are: 1. The development of a malignant tumor at the seat of an old fracture. This same phenomenon I have seen in a number of cases. In one case a child fell upon the back of the head and a sarcoma developed over the seat of a fracture of the occipital bone beneath a large hæmatoma; in another case a sarcoma developed in the line of union of a simple linear fracture of the skull; in still another case after a fracture of the femur. This development of a malignant tumor at the seat of an old fracture is characteristic of sarcoma; because carcinoma never starts primarily in bone; but is always the result of a secondary metastasis. For example, I removed a carcinoma of the breast in a patient some years ago, and within a year from the time of the removal of the breast the same patient fractured her femur while turning over in bed. This specimen I have in my possession, and it forms a unique example of carcinoma in bone from secondary deposit. Epithelioma, however, may arise primarily in a sinus leading to necrosed bone, the result of a compound fracture. In this case the starting-point is not in bone; but in an epithelial-lined sinus with the accompanying irritation, all of which conditions are favorable to the development of this special type of malignant disease. I have one specimen of epithelioma affecting the femur, arising from a condition just described.

2. The second point of interest in this case is the manifestation of the feeling of antipathy to a cutting operation as contrasted with the treatment by caustics. It is precisely in these cases that the surgeon should try to overcome the natural prejudices to an operation; because tampering with caustics and plaster in these cases of sarcoma is never productive of good, but adds additional danger, and hastens the final end. Much encouragement can be given in these days to patients about to undergo the ordeal of a surgical operation, and the surgeon should avail

himself of these arguments to convince kindly and forcibly the patient of his or her error, and persuade these unfortunate and misdirected patients into an operation which is their only safety. In my experience I cannot recall a local recurrence of sarcoma after amputation. This is certainly a most important and encouraging sign, and this fact alone ought to impress upon the surgeon the great necessity of early operation. It ought also to afford a source of great consolation to a patient suffering from this malignant disease.

Finally, I trust that I have been sufficiently clear upon the following points:

1. The importance of early recognizing the disease and the necessity of complete removal of the limb by amputation without delay.

2. The importance of carefully watching the subsequent history of patients upon whom an operation has been performed for the removal of sarcoma.

3. The publication of all cases, whether the result of the amputation was favorable or otherwise, in order to enable surgeons to collect reliable and trustworthy data for future study.

4. The importance of a microscopical examination of every sarcoma. Surgeons are of one opinion upon this point, that a microscopical examination is a *sine qua non* to insure the tabulation of a case for purposes of study.

5. The importance of a radical operation in these cases of malignant sarcomata affecting the long bones of the extremities, and the condemnation of partial enucleations and the use of caustics and plasters.

6. The importance of encouragement to patients suffering from malignant disease of the long bones, on the ground that early and radical operations, even in the most malignant cases, may result in perfect cure.

REMOVAL OF THE UTERINE APPENDAGES FOR DISEASE IN WHICH PAIN IS A PROMINENT SYMPTOM.[1]

By HOWARD A. KELLY, M.D.,
of Philadelphia.

The following remarks are based upon my personal experience, and the results in cases, some of which have been traced for several years, and now may be referred to as permanently cured or improved. Only by *permanency* can any proper estimate be placed upon the value of reported results, and while successful cases are being reported in large numbers daily, within a few days or weeks of the operation, but little has been said of the conditions in which the patients found themselves after one, two, and three years.

My opinion relative to the class of cases suitable for operation, to the results to be expected from operation, and as to the operation upon neurotic cases pure and simple, conforms closely to that expressed by Prof. Hegar in his monograph, *Der Zusammenhang der Geschlechtskrankheiten mit Nervösen Leiden und die Castration bei Neurosen.* Nearly as I agree with Professor Hegar, I differ very widely from many other "authorities," so called, in this much-contested field. Still more widely do I differ from many views which have gained currency in the profession at large, as to the indications for and against operation, the certainty and the permanency and the value of the results obtained.

The convenience of assuming the symptom *pain* as a characteristic factor of the group of heterogeneous cases we are about to consider is at once evident. With this symptom patients usually apply and ask for nothing than that their *pain* be relieved, and under present modes of treatment and indifferent specialization in medicine, in cases even of marked disease of a minor character, the patient often goes through a protracted course of treatment in which nothing is distinct outside of the subjective elements of the case. Pain alone drives most patients to consent to adopt whatever means the surgeon may propose as remedial. By thus emphasizing this subjective feature, and also by the natural history of the diseases, we exclude all those cases from our study in which *size* is a characteristic.

We have left then a great group of mixed pelvic diseases less in size but not in the elements of danger, causing more suffering, with greater certainty undermining the health, and in no sense less important than the large fibroid, dermoid, or ovarian cystoma, unless we measure disease by the tape-measure. "What the eye sees not the heart grieves not," is true of those who find it so difficult to realize the great hourly danger in which their patients may be living, in whom nothing may be apparent to the eye, and but little to an unpractised touch.

Common among the diseases referred to are:

Ovaries enlarged by cirrhosis.

Ovaries with extensive follicular degeneration.

Hemorrhagic ovaries.

Ovaries containing pus sacs.

Neuralgic ovaries.

Ovaries involved in a withering of the pelvic peritoneum with the tubes.

Tubo-ovarian disease with coexisting hydro-, pyo-, or hæmato-salpinx, these three names, however, signifying not the disease itself but an accident of the disease, which may be absent and the disease still exist.

Pyosalpinx is a misnomer, as the disease may exist in all its essentials, and the tube contain no pus, but the ovary may be converted into a large

[1] Read before the Philadelphia County Medical Society, December 28, 1887.

pus sac. In my experience, abscess of the ovary with a tube much thickened, gelatinous and friable on section, but containing no pus, is quite as frequent as a large tube sealed and distended with pus attached to a small ovary simply enveloped in inflammatory products. I believe that the entrance of the septic material into the ovary takes place through a ruptured follicle. In a case upon which I operated one year ago, my patient married a man suffering from gonorrhœa; she experienced no difficulty until the time of her first menstruation, when she was seized with violent pains, and remained an invalid ever after until I removed the mass.

Hydrosalpinx is more commonly associated with some mild non-septic pelvic inflammation which has resulted in sealing the fimbria, and hydrosalpinx results. It may, by distention of the tube, cause pain, but the morbid process usually long antedates the formation of any tumor. If this were not the case, the rational procedure would unquestionably be slitting open the tube on its dorsum, careful removal of the fluid, and an attempt to establish a pervious uterine opening by passing a small canula into the uterus, which could be removed later per vaginam. The disease, however, lies back of this, and the fluid formed is but one of its sequelæ. Here at once is a reason why operations upon tubes thus enlarged are not always and at once successful in curing the patient of all disability.

I am at present making daily visits to a patient operated upon in the Spring, from whom a large hydrosalpinx was removed, along with the ovaries and tube of the opposite side. Her uterus and structures lateral to it are now free from all sign of disease, but there still linger low down in the pelvis foci of inflammation in the cellular tissue, which, although objectively small, cause a disproportionate distress to the patient. The operation was here an imperatively necessary step, but still one step on the road to cure.

Hydrosalpinx is at times associated with anomalies in the development of the individual: thus I operated last week in Chicago on a married woman about thirty-eight, who had been a great sufferer ever since puberty. I found an infantile uterus, two very small, white ovaries, that on the left side being no larger than, and of the shape of, my thumb-nail, while vaulted over it was a large tube distended by several ounces of watery fluid. The indication in this case was not the size of the tube, but the establishment of the menopause to relieve painful ovulation. In pyosalpinx, on the other hand, the starting-point and focus of the disease are often the intensely poisonous contents of the tube, which involve surrounding structures by successive invasions; and here, were it practicable, the disease might often be cured by removing the tube alone, leaving the ovary; but of such a conservatism I do not approve, as the ovary without its duct is useless, even dangerous.

Of hæmatosalpinx I will not speak further than to say emphatically, that I do not believe that all these cases are extrauterine pregnancies, and to draw attention to the fact that the contents of the sac may be as acridly poisonous as that of pyosalpinx, and should receive the same extreme care in removal.

It would be better if *Pain*, per se, were never considered a sufficient indication for operation; or, at the worst, only those cases operated upon in which the most prolonged and painstaking care had failed to relieve, and where the intensity of the suffering must always seriously interfere with the capacity of the patient to enjoy life. We here meet the neurologist on common ground, and it would be better for all such cases if they first underwent a prolonged treatment at the hands of these specialists. A host of cases of neuralgic ovaries which have been sacrificed by the gynecologist would thus have been cured, and many cases which have been operated upon and not relieved would at least have been spared the ordeal of operation, and the too frequent reproach thus be spared the gynecologist, that he recommended the removal of a woman's ovaries, but she declined and a nerve specialist afterward cured her, and, to make the reflection worse, she has since borne a child.

I have a case in which a good friend considered removal of the ovaries would be necessary some two years ago, so great were the patient's sufferings, but with the gradual compensating hypertrophy of an insufficient mitrally diseased heart, she has improved and is now six months pregnant.

A prominent factor in causing this pelvic distress especially aggravated at the menstrual period, is, I am now convinced, large varicose veins in the broad ligaments. I think I can almost always recognize these cases now by the character of the pain, the face of the patient, and a peculiar sense of boggy fulness to the finger on vaginal examination. Constipation seems to be one factor in the causation, but while relieving constipation helps the condition, I have not found that it cures any case of long standing. Sequelæ of pregnancy may cause it. My experience as an operator leads me to reject removal of tubes and ovaries as in any way assisting a cure. In one case sent me by one of the most prominent neurologists in the country last spring, the patient is but little improved, although one of the veins tied and cut off was a half centimetre in diameter. As nothing else seems to do more than mitigate this condition, I propose yet to open the abdomen and simply tie the distended tortuous veins at either end, aspirating then, if necessary, and if the patient is no better she will at least be no worse off.

One class still remains, usually classed among the neuralgic cases, and this class Dr. S. Weir Mitchell

has happily defined, giving appropriate form to an idea which I have for some time entertained. They are those cases in which the expectancy and concentration of the attention on a normal function leads it to simulate disease in the expression of pain. These cases if operated upon rarely reflect credit upon the operator, and should ever be considered more in the province of the neurologist than of the gynecologist. I have never operated on a case of this sort, and never expect to.

We have here been speaking somewhat briefly of cases in which pain is the only local manifestation of disease. There is a small group of cases in which general nervous phenomena of an aggravated character seem after a time to subside into a local disease. I have in mind a case of salaam convulsions which lasted many months, was followed by severe neuralgic pains in various parts of the body, then by severe pelvic pains, and at the operation small cystic ovaries were discovered, and the patient promptly and completely cured by their removal. It is impossible, however, for any but a specialist to distinguish with certainty between those cases in which there are no manifest gross changes in these organs, and the cases about to be described, in which the trained touch can with certainty and exactitude determine the nature and extent of such changes. I know by my own progress in this matter how impossible it is for anything but the touch, which is daily exercising, improving, and correcting its inferences, to come to any definite conclusions in this matter, as to the size and position of the ovary and tube, whether cystic, how much enlarged, and if adherent: all these and other questions are but matters of daily practice for years to decide in all cases.

One of these cases I show you to-night (Mrs. J.) was treated by upward of thirty physicians, and had received almost as many differing opinions, no one recognizing the true nature of her disease, which I had the satisfaction of determining at once to be abscess of the ovary the instant my finger swept over the vault of the vagina. Another patient was treated for fourteen years, and her physician, recognizing some similar symptoms in a case upon which he saw me operating at my private hospital, sent her down to me, and she is now well. Here also I removed ovaries greatly enlarged by old encysted abscesses.

Briefly then, as to the status of this operation—the removal of *diseased* appendages, small in size, but in which pain is a prominent symptom—as a scientific operation.

1. It is scientific, because it deals with *diseased organs*.

2. It does more than almost any other single surgical procedure in relieving a large number of cases whose sufferings have been almost unbearable.

3. In *properly* selected cases the percentage of recoveries is over ninety-five per cent., and improving, and the percentage of cures equally large.

4. Unless we adopt the yardstick as our measure of disease, the indications for operative interference are often more urgent than in the case of most cystomata coming under our observation.

And lastly, all the steps of the operation, the technique of the procedure, have now been so widely appreciated, that it may be described as a *safe* operation.

In marked contrast to this statement might be cited the case of Sir Spencer Wells, in the days when this operation was in its infancy. We can here readily discover one reason why Sir Spencer has always been so bitterly opposed to operations of this class. He operated upon a woman fifty years of age, for the purpose of inducing the menopause. In opening the abdomen the intestine was cut, the ovaries were not completely removed, and the mesentery prolapsed from the wound, and a bad hernia followed. Such was the result of an imperfect technique in the hands of one who in the generation past did more for abdominal surgery than any other man of his time.

Of all questions relative to this work, that of *results* most nearly concerns us. As to the *immediate* result, life or death, I will speak of that under the title of danger of the operation. I refer here to the result relative to the *curing of the disease* in those cases which have recovered from operation. A satisfactory inquiry upon this heading will depend entirely upon the standard which we erect beforehand by which to test our results.

The brilliant results occasionally following this operation, and the many sanguine reports of operations in which the patients are reported to have been the most wretched of all sufferers, and by the abdominal section to have been at once and forever relieved from all pain, to have recovered health at once, and been able to return often to duties of a very laborious nature, have conspired to bring about such a state of professional opinion that cases which cannot show these results are thrown back upon the operator as failures.

There was at one time, when this operation was dangerous, some reason for this opprobrium, and the results gained were measured by the danger passed through, and often found inadequate, but with the great diminution of the danger the whole status of the question has altered. My own standard is this: Are the organs diseased? Will their removal cure the patient entirely, or will it relieve a large part of the suffering and at least make life more bearable. A result *absolutely* good is always to be desired; but a result *relatively* good is something to be very thankful for, and grasped in many cases. Not only the general profession but gynecologists themselves

are apt to place all hope upon the operation, like a throw of dice, and to forget that it is often more rational to handle the cases from the beginning of their treatment to the end, in such a manner that the operation is viewed by doctor and patient as simply a *step* in the treatment and progress toward cure.

Cases often require after-treatment, and some of my cases have only left me entirely well after weeks more of work. My operation removed, it is true, the focus of the disease, without which I could never have made any progress, but my after-treatment dealt with the disease products which may have been accumulating for years, the embers ever freshly kindling so long as the diseased tube and ovary remain, but now readily yielding to treatment. In other cases, I have been actually obliged to deal with disease of my own creating, for in three cases I have treated the women for cellulitic deposits formed, I believe, around the ligature at the stump.

Since my return from Europe on September 7th, I have operated upon fourteen cases of abdominal tumors, including hysterectomy and pyosalpinx. The last case is too recent to speak of, but not one of the others developed any fever after the operation, owing to my careful attention to the principles of antisepsis. A neglect of antiseptic precautions is criminal in any form of surgery. But this may be carried out with nothing but soap and water. The development of an antiseptic conscience is the chief point.

A simple transfixed ligatnre can readily rotate on its point of perforation, releasing the tissues and allowing secondary hemorrhage. To avoid the retraction of the tissues through the ligature, great care must be taken not to cut close to it. One serious error is cupping the stump, which should have an hour-glass form.

Dr. Dudley, of Chicago, uses a knot of his own invention, which I like best of all for most of these cases. It is made by entering the needle, with a double ligature, through the broad ligament, carrying it across, and reintroducing, bringing it out on the same side on which it entered. The needle is removed, and the loop carried over the whole mass to be tied off, and laid between the free ends of the ligatnre. This is grasped in the thumb and fingers, and drawn up tight; then one end is handed to an assistant, while the other is pulled tight, and next the other end treated in the same way, and in the same manner it is tied.

MEDICAL PROGRESS.

Antipyrin as a Uterine Sedative.—M. H. Chouppe has already called attention to the good effects of antipyrin in uterine pains after parturition or in dysmenorrhœa. In proof of this he relates the following case: A woman, aged thirty-five, was suffering from a large myoma situated in the posterior wall of the uterus, accompanied by copious hemorrhage, which reappeared after menstruation. Ergot checked the hemorrhage, but caused such severe uterine pains that it had to be discontinued. Large doses of morphine were administered; these caused the pains to disappear, but at the same time the uterine contraction was relaxed and hemorrhage reappeared. Ergot was again administered with similar results. The attacks of uterine pains lasted two or three hours. M. Chouppe then had recourse to antipyrin. An injection, containing thirty grains of antipyrin, was administered. At the end of twenty minutes the pains disappeared. M. Chouppe then tried the following experiment: An injection of antipyrin was given half an hour before the dose of ergot. The patient experienced no pain, although there was active uterine contraction; hemorrhage was arrested. M. Chouppe concludes that antipyrin relieves the pain caused by uterine contraction which is produced by ergot without diminishing the contraction. He believes that it acts upon the spinal cord, and might be administered with advantage during parturition to women of an irritable temperament.—*British Medical Journal*, December 17, 1887.

Tuberculosis in Infants.—Mantel, in *Le Progrès Médical* of December 10, 1887, concludes that tuberculosis in infants, as in adults, may be accompanied by intra- and extra-pulmonary hemorrhage; intra-pulmonary hemorrhage is more rare among infants than adults. Syphilis and engrafted tuberculosis are a frequent cause of hæmoptysis in infants; the peculiarities of their venous system furnishing an anatomical cause; the mechanism of the process is first the alteration in the child's blood, which causes frequent coagulation in the pulmonary arterioles; the destruction of lung tissue by tuberculosis, and the lessening of oxygenation of the blood; the influence of pleuritic adhesions, which frequently occur, and the pressure exercised by enlarged lymphatics in the mediastina, all conduce to thrombosis of the pulmonary artery, producing areas of passive congestion; syphilis weakens the vascular walls, and in these congested areas hemorrhages frequently occur. The lesions disclosed by post-mortem examination in these cases resemble those in the adult; two are especially interesting, one is the impossibility of discovering the exact source of the hemorrhage, and the other the constant presence of blood in the stomach, in various stages of coagulation, distending that viscus, and illustrating the especial mechanism of hæmoptysis among children. Premonitory and latent hemorrhage, dependent on conditions of the blood, occurs frequently; hemorrhage in any considerable amount is generally an indication of a serious and fatal condition.

The prognosis, in cases in which free hemorrhage occurs, is generally very grave; if syphilis can be discovered and promptly treated, either during or after intra-uterine life, much good may be done.

The Diagnosis of Gonorrhœa in Women.—Noeggerath, of Wiesbaden, concludes an article in the *Deutsche medicinische Wochenschrift* of December 8, 1887, with the following points, on which he bases his diagnosis of gonorrhœa:

1. The illness of a healthy woman occurring soon after marriage, although marriage often disturbs a woman's

health, but should not produce evident symptoms of disease.

2. A purulent discharge, in the absence of deep ulceration, granulation, sarcoma, carcinoma, or scanty, glassy-looking secretion, with small, deep red erosion on the os uteri.

3. Catarrh of the exits of the ducts from the vulvo-vaginal glands.

4. Small, pointed condylomata on different portions of the vulva.

5. A circle of such condylomata about the anus.

6. The presence of colpitis granulosa.

7. The existence of salpingo-perimetritis.

8. Ovaritis.

An Elixir of Saccharin.—Martindale, in the *Pharmaceutical Journal*, proposes the following formula:

Saccharin.	24 grains.
Bicarbonate of sodium .	12 grains.
Alcohol	1 fluid-drachm.
Distilled water . . .	7 fluid-drachms.

The solution of the solids is made in water, the alcohol added, and the solution filtered. Twenty minims contain one grain of saccharin, and this is said to be sufficient to flavor a four ounce mixture.—*Pharmaceutical Record*, December, 1887.

Chloride of Drumine.—Dr. Reid, the introducer of this substance to the profession, reports, in the *Australasian Medical Gazette* for October, 1887, his use of drumine as follows:

A short time ago I had occasion to treat a severe case of sciatica. Having had a little drumine chloride on a filter paper I scraped it off, dissolved it in water, and then filtered it. I injected min. x of the solution, and in half an hour ʒj of solution (strength unknown, as the powder was mixed with filter paper, it was weak, but it paralyzed the sense of taste on the tongue). There was soon great relief, and ease of movement replaced the previous stiff back, so that the patient walked easily down stairs in an hour, when the jarring of ordinary walking formerly gave him much pain. No local or other after-effects appeared, although the powdered drug was over six months old.

Myopia in Russia.—The *British Medical Journal* of December 17, 1887, writes that the Russians appear to be as prone to become myopic as their neighbors the Germans. Prof. Adamyuk, of Kasan, has published in the *Westnik Oftalmologie* a series of examinations of the refraction in pupils at a school. Each pupil was kept under careful observation from his entry into the school until his exit thence. The investigations continued for ten years. Amongst 317 first year's scholars, Prof. Adamyuk found that 165, or 52 per cent., were hypermetropic; 106, or 33 per cent., were emmetropic; and 45, or 14 per cent., were myopic. One case has been rejected out of the total 317. In the course of the year the refraction altered very notably. Myopia made progress in 90 per cent., hypermetropia only in 51.6 per cent., whilst 32 per cent. of the pupils who were emmetropic at the beginning of their school career underwent deterioration of their accommodation, generally in the direction of myopia. Apart from the purely ophthalmological aspect of Prof. Adamyuk's researches, it is interesting to note how a branch of the Aryan race, comparatively young to civilization, are already subject to all those psychological and pathological conditions which have generally been considered to be the essential results of political and social decay in older nationalities. Not only does the Russian mind tend to become excited on complicated questions about Divine right, democracy, or systematic anarchy, State churches or dissent, and other questions so familiar to us, the consideration of which has become part of the very nature of Western Europeans and Americans, but the eyes of young Russians appear to be no stronger in resisting the strain of continuous reading than are the eyes of many Westerns whose ancestors may have been able to read for centuries. Questions of hygiene, however, are connected with disorders of accommodation in schools; and, lastly, though older races may include many individuals who are mentally and physically worn out, young races may not be so ready, as a whole, to bear a strain of intellectual education to which they have not been accustomed.

Antipyrin in Sea-sickness.—Dupuy, in the voyage from Havre to Buenos Ayres and return, has given antipyrin to prevent sea-sickness, with the following results: The dose most generally useful was 23 grains, the effect of which was manifest in about ten minutes. More than 45 grains was never found necessary to procure relief in about an hour.

In rare cases, where the drug was vomited, a hypodermatic injection of 15 grains was efficacious.—*Gazette Hebdomadaire*, December 2, 1887.

Treatment of Blepharitis.—Parinaud advises the following:

Hydrarg. oxid. rubri	3 grs.
Plumbi acetat. (crystall.) . . .	1½ grs.
Vaselin.	ʒ 2½.

The lids may be cleansed by the use of warm solutions of sodium bicarbonate, and a little of the ointment applied. —*L'Union Médicale*, November 29, 1887.

Fatal Tonsillar Hemorrhage.—Dr. Hall writes from Colorado to the *Boston Medical and Surgical Journal* of December 22, 1887, reporting the case of a rancher who suffered from severe hemorrhage at intervals, following quinsy. Improvement followed tonic and astringent treatment; a decomposing clot was expelled, and the affected tonsil returned to its normal size. Eleven days later sudden and excessive hemorrhage occurred, proving rapidly fatal. In the absence of a post mortem, Dr. Hall considers the probable cause of death ulceration and rupture of the carotid artery.

Paralysis of the Abdominal Muscles.—At a meeting of the Paris Société de Chirurgie early in October, M. Deprès exhibited a photograph of a woman whom two medical attendants had believed to be subject to ovarian disease. The abdomen was extremely pendulous, and measured forty-eight inches round the umbilical level. On careful examination M. Deprès found that the umbilical muscles were entirely paralyzed. The patient could not rise from her bed without supporting the abdomen with her hands. No contraction of the muscles occurred during movement or coughing, nor under any

form of electrical stimulation. Frequent pregnancies often cause distention, thinning, and consequent weakening of the abdominal muscles, but never paralysis. M. Deprès's patient had been only twice pregnant, and the labors were normal. In the discussion which followed, M. Lannelongue stated that he had seen paralysis of the abdominal muscles in anterior poliomyelitis, but without the symptoms noted in M. Deprès's case. M. Marc Sée believed that the pendulous abdomen was certainly most frequent amongst multiparæ, but had been observed in women who had borne only one child. M. Deprès replied that he had seen numerous cases of pendulous abdomen which simulated ovarian disease, but never, before this example, any instance of paralysis of the abdominal muscles which had caused symptoms mistaken for those observed in cystic tumors of the ovary. The case was certainly of great interest. Pendulous abdomen is a well-known affection; Landau has recently written an able treatise on its nature and treatment, and its due recognition is of importance to physicians and surgeons, as well as to obstetricians. A cursory glance or sweep of the hand over a pendulous abdomen may give rise to a serious error of diagnosis. Ascites, pregnancy, ovarian or uterine tumor may be suspected, especially when the walls are very thick, so as to interfere with resonance on percussion. In cold weather, or when the hand of the observer feels chilly, contractions of the recti are set up, and may give the erroneous impression that some solid growth is present. The support of a belt gives comfort, and to a certain extent cures the affection. Here we may note that Mr. Treves has recently declared that the belt is not advisable after ovariotomy and allied operations, as it interferes with the natural process of recovery which the muscles, weakened by long distention, would undergo if left to support themselves. However, many experienced authorities would dread the abolition of the abdominal belt after abdominal section, for hernia of the cicatrix is not rare; indeed, Dr. Homans, of Boston, discovered that it ultimately developed in ten per cent. of his patients, and those who are as careful about after-histories as Dr. Homans would possibly find their proportions just as high. Thus the question of the means of making the abdominal walls as strong as possible after an operation becomes very important, and the relative merits of Mr. Treves's principles and the usual practice deserve deep consideration. The case of true paralysis of the abdominal muscles described by M. Deprès must not be overlooked, since it is a condition which we may safely say has been frequently confounded with a simple pendulous condition of the abdominal walls.—*British Medical Journal*, Dec. 17, 1887.

Conservative Divulsion of the Cervix Uteri.—In the *St. Louis Medical Review* of December 17, 1887, DR. HULBERT reports elaborate calculations which he has made regarding the physiology of menstruation, and the amount of fluid which is expelled through a normal cervix. He concludes that in dysmenorrhœa from mechanical causes stenosis is infrequent, and that the operation of divulsion is allowable only when confined within the physiological limits of the tissues acted upon.

Mental Affections and Aural Disease.—Sufferers from noises in the ears are sometimes greatly distressed by the tinnitus, and cases of suicide have been ascribed to sheer desperation resulting from an inability to get relief from the everlasting noise. Ménière's disease and some cases of epilepsy are attributed to disease in the ear setting up changes in the central nervous system. The question is still unanswered whether actual mental disease, mania, or melancholy, may not be produced by aural disease, apart from any annoyance due to tinnitus or deafness. Coarse diseases, such as otorrhœa, suppuration in the mastoid cells, perforations of the drum, polypi, waxy concretions, and foreign bodies, are easy of recognition and can be appropriately treated, generally by simple surgical methods. But nervous affections due to irradiation from the obscure aural mischief are not always so open to treatment, because the changes in the ear are more subtle, but none the less real. Sometimes an obstruction of the Eustachian tube may be the chief cause of tinnitus, owing to unpoised atmospheric pressure leading to excitation of the labyrinth and acoustic nerve by actual compression. M. Boucheron believes that, besides vertigo, epilepsy, and other nerve troubles, mental disease may be originated, and simple inflation of the middle ear has been followed by a cure.—*Lancet*, December 17, 1887.

Cancer of the Larynx.—At a recent meeting of the Academy of Medicine of Paris, RUAULT reported the case of a man, sixty-three years old, who suffered from epithelioma on the right lower vocal cord. The symptoms gradually appeared during ten months' time. Laryngoscopic examination established a diagnosis several days after the tumor began to ulcerate. The general condition of the patient was excellent; the growth was circumscribed; there was no glandular swelling. The surgeon decided to perform thyrotomy, and partial laryngectomy if needed. Tracheotomy was first made, but the patient died of pneumonia two days afterward. The autopsy and microscopic examination showed a lobulated, warty carcinoma, exactly limited to the ligamentous portion of the lower vocal cord, of which the anterior and posterior extremities were healthy for a considerable extent. The conclusion reached was that the partial excision, if carried out, would have resulted in cure. Early diagnosis is of the greatest importance, and early operation.—*L'Abeille Médicale*, December 12, 1887.

A Convenient Mixture for Toothache.—From *L'Union Médicale* of December 1, 1887, we take the following:

Ext. opii (alcohol),		
Camphor. pulver.,		
Balsam. Peruvian. . . .	āā	8 grs.
Resin. mastich.		15 "
Chloroform.		3 2½.

A solution to be made; in which a pledget of cotton is to be dipped, and inserted in the tooth.

Acute Thyroiditis.—The thyroid gland may be the seat of an acute inflammatory enlargement running a definite course without suppuration and terminating in perfect recovery. In these clinical characters we find a resemblance to ordinary mumps. Dr. Barlow read a paper on "Acute Enlargement of the Thyroid Gland," at the last meeting of the Clinical Society, and he related the case of a little boy, aged three, in whose thyroid gland an attack of inflammation occurred, which lasted altogether about a fortnight. The child had just previously suffered

from erythema nodosum on the legs, and it was whilst recovering from this affection, and after having been out in the park, that the thyroid enlargement commenced in association with a nasal catarrh, of which the chief symptom was a discharge of thin glairy mucus. Reviewing the literature of the subject, Dr. Barlow arrived at the conclusion that his case must be regarded as coming under the "idiopathic" class of Lucæ, and although there had been erythema nodosum, still the absence of arthritis and heart disease or other genuine rheumatic manifestations formed a warranty for not considering the case as of true rheumatic nature. Some observers, chiefly abroad, have noted a rheumatic swelling of the thyroid having a definite relationship with well-founded rheumatism; and Dr. Angel Money quoted a case of this character from his own experience. Mr. James Berry narrated many interesting particulars concerning acute enlargement of the thyroid gland; and some of these having a fatal ending might tally with cases like the one narrated by Dr. Barlow, in which the enlargement at one time had a threatening aspect. Nevertheless, the definite cycle run by cases of rheumatic and idiopathic descriptions must, we think, be held to differentiate them from ordinary goitre, in which the mode of commencement may be acute, but the course always chronic, and showing recurrent tendencies. The perusal of Dr. Barlow's paper will raise the reflection that the causation of acute thyroid enlargement is as imperfectly known as it is seemingly various.—*Lancet*, December 17, 1887.

A Curious Accident.—Dr. Pringle reports, in the *Edinburgh Medical Journal* for December, 1887, the case of a man, aged twenty-two, who was admitted to the Royal Infirmary, having sustained the following accident: He was employed in a sawmill in the city, and it was his duty to guide the piece of wood which was being sawn. While at his work that morning, a board which had just been cut from a log, from some cause unexplained, came in contact with the teeth of the saw, which was revolving at a rate, at its circumference, of 4000 feet per minute. The end of the board nearest the patient was smashed into splinters, only two of which, however, were torn completely off it; these two struck the patient with tremendous violence just below the nasal bones. The appearance presented by the patient at the time of his admission was a most ghastly and extraordinary one.

From the articulation between the nasal bones and cartilages there was a lacerated wound, at the bottom of which the superior maxilla was exposed, running down to the right angle of the lower jaw, and passing one inch above the angle of the mouth. From just below the nasal bones the two splinters of wood projected, the shorter passed straight back through the nasal cavity, the longer down under the cheek, and projected the skin at the left angle of the lower jaw. The patient was so violent that he had to be put under the influence of chloroform until Mr. Annandale's arrival. The longer of the two splinters was easily removed, but the shorter was wedged as firm as a rock, and to get it out Mr. Annandale had to split the hard palate with a chisel introduced through the wound, and so lever the superior maxillæ apart, and even then it required considerable force to extract it. There was comparatively little hemorrhage. The nasal cavity was plugged with lint and the wound stitched up. His pulse was very feeble and rapid; his respirations forty per minute, and rather difficult. As the soft palate was somewhat swollen, a tent and bronchitis kettle were got up, and an ice-bag applied to his head. At 12 o'clock his breathing suddenly became very labored, and patient cyanotic. Tracheotomy was performed with immediate relief. On passing the finger into the mouth, the soft palate was felt to be so much swollen that it almost entirely obliterated the fauces. At 8 P. M. his breathing had become Cheyne-Stokes in character, and sixty per minute; his pulse so rapid and feeble that it could not be counted. He lingered on and died at 4 A. M. next morning, never having regained consciousness.

Post-mortem.—The turbinated bones, vomer, and right superior maxilla comminuted. The hard palate was transversely fractured, but the mucous membrane not involved. Epiglottis and back of tongue seemed normal; soft palate slightly lacerated. Lungs extremely congested and œdematous, but so altered by putrefactive changes, that it was not possible to say if blood had been inspired. The membranes of the brain injected. The brain had received no injury; there was no fracture of the base of the skull. The longer of the two splinters measured fourteen inches in length, and was half an inch thick, and tapered from a point half an inch by half an inch to the other end, which measured half an inch thick by one inch broad; it had entered to a distance of three inches. The shorter one measured five and a half inches long; its *larger* end, *which was the one which entered*, measured three-quarters by half an inch, and there was only three-quarters of an inch projecting beyond the soft parts, leaving four and three-quarters inches buried in the nasal cavity.

"Arsenic Cancer."—As the mind is naturally caught by the curious and by the threatening, so we cannot avoid alluding to the subject which Mr. Jonathan Hutchinson raised at the last meeting of the Pathological Society. We fear, however, that at present further light is required before our knowledge can be considered satisfactory. Many amongst us having a strong belief in the efficacy of arsenic know well its power to produce disease; but, judged from the discussion at the Pathological Society, some do not appreciate the influence of arsenic on the skin. The skin *par excellence* is the tissue on which arsenic has perhaps its most marked influence; besides improving, it may spoil the complexion, rendering it muddy and unsightly. This latter action is also manifested in all parts of the skin, and may lead to the development of soft corns, not warts, in the palms of the hand and soles of the feet, where a roughened condition also grows up under the influence of this most potent drug. So far Mr. Jonathan Hutchinson goes with safe step on sure ground, but the next move onward toward the belief that arsenic can produce epithelial cancer is less secure. It cannot be said outright that arsenic may be the chief cause of epithelial cancer, but we think the position almost impregnable if it be maintained, as, indeed, Sir James Paget and Mr. Hutchinson strongly held, that arsenic may prove one of the causes of epithelial cancer in certain constitutions. Nevertheless, arsenic will not fall into disrepute, for at the worst it is only when continued for many years in very full doses that the drug is alleged to have so deleterious an action. Such a revelation, if it ever comes, will only make medical practitioners more careful in prescribing arsenic.—*Lancet*, December 17, 1887.

Acute Pulmonary Paresis.—At the last meeting of the Medical Society of London, DR. B. W. RICHARDSON called attention to a class of cases presenting such peculiar features as to warrant, in his opinion, the belief that the symptoms are due to a loss of nerve power, resulting in acute vasomotor paralysis of the vessels in the pulmonary area. Though not common, most practitioners must be able to call to mind cases, diagnosticated as pneumonia, where the patient rapidly dies of asphyxia in spite of all that can be done to check the morbid process. The cases alluded to by Dr. Richardson were mostly in women of a neurotic type. Under the influence of a physical or moral shock, not necessarily of any great intensity, nervous phenomena of a hysterical type manifest themselves, followed by intense prostration of body and mind. In the course of a day or two, examination reveals the advent of pneumonic *râles*, and then, without fever, for the most part without pain, and without many of the characteristic signs and symptoms of ordinary pneumonia, the patient rapidly succumbs. Treatment in every case is utterly without avail. Not less interesting than the observations so carefully narrated, are Dr. Richardson's remarks on the effect of nitrite of amyl in bringing about an identical condition of things in animals submitted to its influence. The pathological phenomena are those which physiology teaches us result from section of the nerves which innervate the lungs; and, on this ground, Dr. Richardson argues that the asphyxial phenomena which terminate the rapid and fatal course of this redoubtable disease are attributable to a sudden suppression of nerve power. It could hardly be anticipated that this addition to medical nomenclature would pass unchallenged; and, while the paper will certainly call attention to a class of cases hitherto very imperfectly understood, his views evidently failed to find acceptance on the grounds put forward in their behalf. It appears certain that, to explain the sudden and violent breaking down which is met with in certain cases of so-called pneumonia, either some influence must have been superadded to the usual processes, or we must look to another category of causes altogether to account for the collapse.

Hypnotic Suggestion in Nicotinism.—At a recent meeting of the French Anti-tobacco Society, DECROIX compared the appetite for tobacco to that for alcohol, and suggested hypnotic suggestion as a remedy. VOISIN also reported cases which had been cured by this means after other remedies had utterly failed.—*L'Abeille Médicale*, December 12, 1887.

Sterility in the Male.—DR. KEHRER, of Heidelberg, has recently published some researches on this obscure subject in a work entitled *Beiträge zur Klinischen und Experimentellen Geburtskunde und Gynäkologie*. To 40 already reported cases of sterile marriages where he had examined the semen, he has added 56 more. In 3.12 per cent. complete impotence was certain; in 30.21 per cent. the semen did not contain spermatozoa (*Azoospermia*); in 11.45 per cent. these organisms were deficient in quantity (*Oligozoospermia*), and in 55.20 per cent. they were present in abundance (*Polyzoospermia*). Amongst the cases of azoospermia, in many instances no cause for the anomaly could be traced; in a fifth masturbation had avowedly been practised; in more than two-thirds the subjects had suffered from gonorrhœa, but disease of one or both testicles could not be detected in many of these patients, so that Dr. Kehrer suspects other complications besides disease of the epididymis, such as obstruction of the ejaculatory duct through prostatitis, or fatty degeneration of the tubuli seminiferi. The proportion of subjects where there had been gonorrhœa was the same in the cases of oligozoospermia, where yet a chance of fruitful coitus remained, whilst amongst the sterile men where polyzoospermia was discovered, only half as many had been subject to gonorrhœa. Dr. Kehrer believes, judging from his researches, that in at least a third of the cases of sterile marriages the husband was the party at fault, and gonorrhœa was the primary cause of the barrenness. Here it must be remembered that, unfortunately, that disease is extremely common amongst young unmarried men, and in making researches in long series of fertile marriages, a large proportion of the husbands would probably be found to have suffered from gonorrhœa. Noegerrath fell into a doubtful line of argument somewhat like that of Dr. Kehrer, and Bumstead, amongst others, exposed the fallacy. Dr. Kehrer believes that other sources of sterility will yet be discovered, such as influences directly prejudicial to the germ-cell or sperm-cell.—*British Medical Journal*, Dec. 17, 1887.

Bacteriology of Smallpox.—PROFESSOR J. HLAVA describes in the *Sbornik Lekarsky*, a Bohemian medical journal, the results of some microscopical and bacteriological researches he has lately made on the contents of variolous pustules and the blood and viscera of smallpox patients. In four out of five cases streptococcus pyogenes was found in the blood and viscera. In the skin and in the pustular contents there were found, in addition, staphylycoccus albus, saccharomyces (Proteus Zenkeri), and staphylococcus citreus cereus. The identity of the microörganisms found with pyogenic microbes was demonstrated experimentally, but none of them produced smallpox. Professor Hlava believes that the variolous poison produces characteristic changes in the epithelium of the skin, and that in consequence of these pyogenic cocci invade the dermis, being carried thither by the circulation, which they enter through abrasions of the surface of the pharynx and larynx, which, he says, are invariably to be met with in smallpox patients. Thus variola would appear to be, in the majority of cases, a disease due to a mixture of infections, variolous and pyogenic, the latter class of infection entering the body subsequently to the former.—*Lancet*, December 17, 1887.

Antipyrin in Hæmoptysis.—In the *Meditzinskoïe Obozreniïe*, No. 5, 1887, p. 520, DR. M. BYVALKEVITCH, of the Vilna Military Hospital, states that antipyrin is an excellent remedy for pulmonary hemorrhage of every kind. The statement is based on ten cases of hæmoptysis in patients suffering from phthisis, bronchiectasis, cardiac disease, and traumatic injury of the chest. The following mixture was invariably employed by Dr. Byvalkevitch: R.—Antipyrini, ℥ss; aq. destil., ℥iv; essentiæ menthæ pip., gtt. xv. M.D.S. A tablespoonful every two or three hours. In none of the cases were more than two doses of the mixture required completely to arrest hæmoptysis, even when the daily loss of blood amounted to two fluid pounds. In some of the patients ordinary hæmostatics, such as ergot, ergotin, digitalis, atropine, and Haller's elixir, had been previously tried without effect.—*British Medical Journal*, December 17, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JANUARY 14, 1888.

SUPRAPUBIC LITHOTOMY IN MALE CHILDREN.

By far the most noteworthy contribution of the past year to the operative surgery of vesical calculus is that of ASSENDELFT, of Wetoschkino, Russia, who reports, in the *Archiv für klinische Chirurgie*, Bd. xxxvi., Hefte 1 and 2, the details of one hundred and two cases of epicystotomy for stone, with only two deaths, a success which is as wonderful as it is unparalleled. As not less than eighty-one of the subjects were male children, among whom the two deaths were met—one from peritonitis, and the other from purulent bronchitis, their ages having been, respectively, two and four years—we propose to set before our readers an analysis of the results attained by Assendelft, and compare them with those afforded by litholapaxy and lateral lithotomy in the same class of subjects.

The age of 38 patients varied from two to five years inclusive; 27 were between six and ten years inclusive; and 16 ranged between eleven and fifteen inclusive. The hospital in which they were treated was in an excellent sanitary condition. The steps of the operation are as follows: A catheter having been inserted into the bladder, enough of a one-half per cent. carbolic acid solution is thrown into the viscus to render it prominent above the pubes. The Garson-Petersen rectal bag is dispensed with, but the catheter is retained to facilitate the future steps of the operation. The incision in the linea alba is carried from just below the border of the symphysis pubis upward for a distance which varies between an inch and three-quarters and three inches, from one and three-quarters to two inches being, as a rule, sufficient. The prevesical space having been exposed, its fatty tissues are divided until the bladder is reached, care being taken to avoid the veins, or to ligate them should it become necessary. The bladder, previously fixed with tenacula, is opened from above downward with a sharp knife, the incision varying in length from four-fifths of an inch to one inch for small stones, or extending to two and a quarter inches for large concretions. If in this step of the operation the peritoneum should be seen, it is held back by the index finger. Any bleeding from the vessels of the bladder having been arrested, which is not always easily done, the stone is extracted with the finger or the forceps, avoiding, if possible, its fracture, which is liable to provoke hemorrhage from the vesical mucous membrane. The bladder is now washed out with a one-quarter per cent. carbolic solution, and a one-third of an inch drainage tube, or two smaller tubes, passed into its cavity, and fixed by Carlsbad pins. The divided recti muscles, or their sheaths, as well as the skin, are approximated by catgut sutures to the point of exit of the drains. The wound is powdered with iodoform, and covered with iodoform and salicylic gauze, which are properly secured in position, and the patient is placed upon his belly, with the head elevated by a small pillow, a position to which he soon becomes accustomed.

For the first four or five days the dressings are changed from six to eight times in the twenty-four hours. At the end of this time a smaller drain is employed, or if two were inserted originally, one is omitted. As soon as the patient begins to pass urine by the urethra, which happens, on an average, in nine or ten days, drainage is dispensed with, and the patient can lie on his back. Complete cicatrization of the wound occurs, exceptionally, as early as the sixteenth or eighteenth day; but it may be delayed for four or even five months, the average being thirty-seven days.

The peritoneum was seen in the upper angle of the wound in 19, or nearly 24 per cent. of the cases, and it is interesting to note that 76.47 per cent. of the subjects were between two and five years inclusive; 17.64 per cent. were six years of age; and 5.88 per cent. were seven years of age. These observations indicate how slight are the risks of wounding that membrane during the operation; and they tend to confirm the statement of Pitha, that after eight years the peritoneum descends only one or two lines

below the umbilicus. The fact that the bladder is still an abdominal organ up to eighteen years, through which a large surface is uncovered by peritoneum, renders impubic subjects peculiarly fitted for epicystotomy. Hence, the Petersen bag may be dispensed with.

Among the primary risks of the operation, hemorrhage was the most common. In 6 cases there was free bleeding from the arteries of the bladder-wound; in 2 from the mucous membrane of that organ; and in 1 from the prevesical space. In 4 cases there was reactionary hemorrhage. In 3 secondary bleeding was encountered, in 2 of which it was so serious as to necessitate reopening of the wound, and plugging with iodoform gauze. Phlegmonous inflammation of the groin and of the penis, and necrosis of the tissues of the prevesical space were witnessed, each, in 1 case. In 3 cases there was peritonitis, and one of these proved fatal. In not less than 29 of 61 cases in which the details are perfect, the edges of the wound separated, the separation being partial in 6, and complete in 23. This complication may be set to the account of the catgut sutures employed for sewing up the wound. In 9 examples hernia of the mucous membrane of the bladder rendered extraction of the stone difficult. In several of the cases the patients were so ill that they barely escaped with their lives.

As the natural outcome of his wonderful success—the mortality having been only 2.47 per cent.—Assendelft recommends the adoption of suprapubic lithotomy to the exclusion of other procedures: but the success of any operation should not be based upon the practice of a single surgeon. We happen to have notes of 90 additional antiseptic, suprapubic lithotomies in impubic boys. Of these 20 perished—a mortality of 22.22 per cent.—13 from peritonitis, 3 from prevesical phlegmon, 1 from urinary infiltration, 1 from purulent nephritis, while we are unable to state the cause of death in the remaining 2. Of these 90 cases, Schmitz, of St. Petersburg, had 23 with 5 deaths, a mortality of 21.73 per cent. Adding the 90 additional cases to the 81 of Assendelft, 171 cases afforded 22 deaths, or a mortality of 12.86 per cent., which must be regarded as the proper death-rate of antiseptic epicystotomy for calculus in boys.

Better results than those of Assendelft have been attained from other procedures by other operators. Thus, Surgeon-Major Keegan, of Indore, about a year ago published a table of 58 cases of Bigelow's operation in male children whose ages ranged from twenty-one months to fourteen years, with one death, or a mortality of 1.72 per cent. The ages of 46.53 per cent. of his patients varied from less than two to five years inclusive; 41.37 per cent. were between six and ten years inclusive; and 12.07 per cent. ranged between eleven and fourteen inclusive. For the same period Assendelft's cases showed, respectively, 46.49, 33.33, and 19.75 per cent. In Keegan's cases the stone weighed less than fifty grains in 46.42 per cent., between fifty and a hundred grains in 16.07 per cent., up to two hundred grains in 19.64 per cent., and above two hundred grains in 17.87 per cent. In Assendelft's cases the same weights are represented by 38.27, 17.29, 22.22, and 22.22 per cent. Hence, Keegan crushed more subjects of tender years than Assendelft cut, although the stones in the cases of the latter were, as a rule, more bulky.

Turning from litholapaxy to lateral lithotomy, still more satisfactory results than those of Assendelft's are shown by Freyer, who cut 165 boys without a single death, and by the surgeons of the Children's Hospital of Moscow, whose last 72 cases, according to Werewkin, were all successful and yet there is no more reason for recommending the exclusive adoption of lateral lithotomy in boys than there is for the exclusive resort to epicystotomy or rapid lithotrity. As yet the last operation has not been sufficiently tried, so that a comparison can only be drawn between the first two procedures as practised in late years. As we have already seen, antiseptic suprapubic lithotomy is attended with a mortality of 12.86 per cent., and requires thirty-seven days for the healing of the wound. Freyer's 165 cases of lateral lithotomy, all successful; Ramnarain Dass's 87 cases, with 3 deaths: S. D. Gross's 72 cases, with 2 deaths; Rosenthal's 203 cases, with 13 deaths; Kovac's 57 cases, with 3 deaths; Post's 106 cases, with 2 deaths; and 147 cases, with 9 deaths, in the Children's Hospital of Moscow, afford 837 cases, with 32 deaths, or a mortality of 3.82 per cent. Add to this seventeen days for healing of the wound, and the advantages are all on the side of the perineal operation.

If the surgeon were forced to limit himself to one procedure, he should choose lateral lithotomy; but the wise operator will select his cases, reserving epicystotomy for large calculi and encysted calculi. The latter method is being carried to an unwarrantable extreme by German and French surgeons. We daily read cases in which it is practised for stones which weigh eight, ten, fifteen, or twenty grains, and

which could have been safely crushed or removed through the perineum, instead of subjecting the patient to greater risks and to a more prolonged confinement.

In conclusion, we may be allowed to express the opinion that, in the present state of our knowledge, a stone in a boy should be removed by the lateral method, with the reservation that after the age of seven, if the concretion be of moderate dimensions, the median will be the safer procedure; while a large calculus at any age will call for the high operation. Should the last of these methods be selected in view of its comparative success in children, suture of the bladder should be practised, and a drain retained in the prevesical space. If the vesical wound should reopen, nothing will have been lost; should it remain closed, the subsequent treatment will be greatly shortened, and the patient will be spared the inconvenience of lying on his belly. In point of fact, if there be no cystitis, and the urine be clear, suturing the bladder will, as a rule, be attended with primary union. It ought also to be added that the superficial wound should be approximated down to the drain with the continuous silk aseptic suture, to guard against its reopening, as happened so frequently after the use of catgut in the cases recorded by Assendelft.

FREE HYDROCHLORIC ACID IN THE STOMACH.

The diagnostic importance of testing the stomach contents for free hydrochloric acid, to which attention was called in The Medical News of August 20, 1887, is beginning to be recognized, as is evidenced by its recent employment in some of our hospitals, and it may be useful for us now to point to certain sources of error that may vitiate the results thus obtained, and also to state that Dr. Alfred Günzburg, of Frankfort-on-the-Main, has recently discovered another test, which is claimed to be free from some of the objections of which we previously hinted. As an instance of the latter, gentian-violet, which is, perhaps, the best of the substances hitherto used to detect free hydrochloric acid in the gastric juice, gives the same reactions when the organic acids, especially lactic, are present in large amount. The same is true of tropæolin and Congo red; hence obvious sources of error.

The test about to be described is based on the discovery by Wiesner that pine wood dipped in a solution of phloroglucin, and then moistened with concentrated hydrochloric acid, is colored a dark red. Max Singer ascertained that the substance in the wood which, when in contact with phloroglucin and hydrochloric acid, strikes a red color, is vanillin. The reaction was studied more minutely by Etti, who found that pyrogallol, in the presence of vanillin and hydrochloric acid, behaved much in the same way as phloroglucin.

For the sake of convenience, Günzburg selected phloroglucin for his test, which is as follows: Thirty grains of phloroglucin and fifteen grains of Merck's vanillin in about an ounce of absolute alcohol, make a yellowish-red solution. A trace of concentrated mineral acid added to this solution produces a bright red color, and, at the same time, there takes place a separation of beautiful red crystals. Concentrated organic acids (lactic and acetic), either alone or mingled with chlorides, give no such reaction. The mineral acid to which the reaction is due must be concentrated. If diluted, the color does not appear until some of the fluid is driven away by heat, when the red crystals appear. *Boiling must be carefully avoided.*

The following is the technique for application to the examination of the stomach contents: A few drops of the filtrate of the latter are mingled in a porcelain dish with the same quantity of phloroglucin-vanillin solution, and carefully heated. According to Günzburg, the reaction will take place invariably if one-tenth of one per cent. of free hydrochloric acid be present, a delicacy at least equal to that of the aniline solutions. If but one-twentieth of one per cent. of the acid be present, the reaction occurs in the form of red streaks, and below this degree it ceases altogether. Günzburg is of the opinion that a quantitative estimate of the amount of hydrochloric acid may be made in accordance with the intensity of the reaction, but it is doubtful whether any near approach to accuracy could thus be obtained.

THE DIURETIC INFLUENCE OF STROPHANTHUS.

So much has appeared in the journals during the last few months concerning strophanthus and its effects on the heart, that its action on the rest of the system has been overlooked. In the *Gazette Hebdomadaire* of December 9, 1887, Mairet and Combemale give us the result of their studies on its action on the secretion of urine and the elimination of urea. They found that the quantity of urine was considerably increased, and that the urea, while not always altered in amount, was generally increased.

This occurred when the drug was used by the stomach or hypodermatically. As to its action on the kidney they found that it increases the urinary flow both by mechanical pressure, due to greater arterial tension, and also by a direct stimulation of the secreting structure of the kidney.

Both of these investigators believe that cumulative effects do not occur after the prolonged use of strophanthus, but until the drug has been more widely used we doubt whether this statement can be received as proven. So little is known as to the renal effects of the drug that it is possible that it may be too irritating to use constantly in case of kidney lesions, particularly of an acute and active type, and all the evidence points to its use in cardiac lesions rather than those of the renal tissues.

RECOVERY IN CIRRHOSIS OF THE LIVER.

IN THE MEDICAL NEWS of September 18, 1886, we referred to a discussion which had taken place at one of the Paris societies on the subject of the curability of cirrhosis of the liver, and the case recently reported in THE MEDICAL NEWS, by DR. MACDONNELL in the proceedings of the Montreal Medico-Chirurgical Society, illustrates a point in practice which is too frequently overlooked. It is still customary with many physicians to defer tapping in hydroperitoneum until diuretics and cathartics have been thoroughly tried, and the trocar is resorted to only when the distention has become extreme. The late DR. FLINT was, we believe, the first to advocate early and repeated tapping in this condition, and in his work on clinical medicine he refers to several cases in which in years no reaccumulation of fluid took place. Dr. Macdonnell's patient was tapped sixty times within a year, and after about 9000 ounces of fluid had been removed no reaccumulation occurred, and the woman apparently got well. Continuous drainage has also been practised with good results.

The factor which determines the onset of dropsy in cirrhosis of the liver is not always clear. The highest possible grade of portal obstruction, even obliteration of the vena portæ, may exist without it, and a rich development of anastomosing vessels may compensate fully the destruction of branches within the liver. At least one-third of all cases of the ordinary atrophic cirrhosis are met with accidentally on the post-mortem table in persons dead of other affections. So long as an active collateral circulation is maintained there may be no symptoms. When we consider the extraordinary capacity of the abdominal vessels and the variations in blood supply to which they are liable, we can readily understand that conditions of distention of the portal radicles might arise with which the collateral circulation could not cope; and a sudden hematemesis or the development of ascites would represent a failure in a compensation hitherto effective. It is possible, as some writers have suggested, that owing to changes in the serous layer the capillaries are rendered more permeable and without any increase in the blood pressure permit of the transudation.

The practical point is this, that in certain cases of cirrhosis the effusion results from changes which are not necessarily permanent, and we should not regard the onset of dropsy in every case as the beginning of the end. Clinical records point to early and frequent tapping as the very best measure in ascites, not only as affording immediate relief to unpleasant or urgent symptoms, but as holding out a prospect in some cases of the removal of the conditions on which it depends.

THE South Carolina Medical Society celebrated its ninety-eighth anniversary on the evening of December 12th. As is the custom, new officers were elected as follows:

President, Dr. Manning Simons; *Vice-president*, Dr. T. Grange Simons; *Treasurer*, Dr. John L. Dawson, Jr.; *Secretary*, Dr. Charles W. Kollock. After the meeting, a handsome supper was served at the Charleston Hotel.

This is not the State Society as its name might indicate, but is the County Medical Society.

The new Charleston City Hospital is rapidly nearing completion, and the site chosen on the banks of the Ashley is in every way desirable.

THE New York Academy of Medicine has received another accession to its library of five thousand volumes by the gift of the late Dr. Middleton Goldsmith, formerly of New York and Louisville, but latterly of Rutland, Vermont, where he died in November last. Dr. Goldsmith's name will be recalled by many in connection with his plan of treatment of hospital gangrene by bromine; he was also an early advocate for the pavilion hospital during the late war. His gift of books was made shortly before his death, through his old friend, Dr. John C. Peters, of New York. So many of these newly acquired books as are already in the reference department of the Academy library will be placed in its circulating branch.

The Crown Prince is said to be improving in respect of the diminution in size of the laryngeal growths; but, inasmuch as the damp weather at San Remo has compelled him to remain indoors so much of the time, it is probable that he will go to Cairo for the remainder of the winter.

From Berlin, we learn that Prof. Virchow is making a careful study of all the pathological specimens within his reach, for the purpose of discovering if there has ever existed a case in which a benign growth and a cancerous one have grown up side by side. He has as yet found no instance of that nature; and, inasmuch as he has never found any malignant characteristics in the three specimens from the Prince removed by Mackenzie, he infers that the new formations, of which no microscopic examination has been made, are likewise non-malignant.

REVIEWS.

A Manual of Medical Jurisprudence, for the Use of Students at Law and of Medicine. By Marshall D. Ewell, M.D., LL.D., Professor of Common Law in Union College of Law, Chicago, Ill. 12mo. pp. 409. Boston: Little, Brown & Co., 1887.

A somewhat careful perusal of this little work has left a very favorable impression of its general soundness, and of its adaptation to the wants of the busy student and practitioner, both of law and medicine.

The author, in his preface, modestly disclaims for it anything more than a "careful compilation of what seemed to be the best authorities of the leading principles of the science." He has certainly shown a diligent and careful study of these leading authorities; especially appealing to Drs. Tidy, Ogston, and Spitzka—the latter being his chief authority on insanity.

The limits of his volume preclude any allusion to *special* Toxicology, but his observations on Poisoning in general are sufficiently plain and practical; and, although necessarily much condensed, they embrace what is really essential to the general student.

One criticism we would offer in relation to the *guaiacum-test* for blood. The author, after correctly stating the method of applying this test, reminds the reader that many other substances besides blood will produce a blue discoloration with guaiacum. This statement, while true, is slightly obscure, and might lead to an erroneous impression: the fact being, that whilst all these other substances do occasion the blueing of the guaiacum, blood will *not* change its color immediately, when used alone, *but only on the addition of hydrogen peroxide.*

The author, in common with most authorities, is of the opinion that it is impossible to distinguish the human blood-corpuscles from those of the lower mammalia; and while quoting the late Prof. Joseph G. Richardson's microscopic researches on this subject, he omits to mention his very positive assurances and proofs of being able, by the use of very high powers to discriminate with great certainty between human blood and that of the more common domestic animals with which it would be most likely to be confounded in a murder case, viz., the sheep, cow, horse, goat and hog. This fact is certainly worthy of consideration by the medical jurist, and its accuracy has been verified by the present writer.

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, December 28, 1887.

The President, J. Solis-Cohen, M.D., in the Chair.

Dr. Howard A. Kelly read a paper on

THE REMOVAL OF THE UTERINE APPENDAGES FOR DISEASE IN WHICH PAIN IS A PROMINENT SYMPTOM.

(See page 36.)

Dr. John C. DaCosta believed that many unnecessary operations are done, and that it is better practice to cure a woman and leave her with her organs intact, rather than by a brilliant operation to unsex her, without the certainty and with only the hope of relief. He took decided ground against the great number of abdominal sections now being made, including those made for "pain alone." He held that a large proportion of the operations as done, and for the reasons alleged for operating, are unjustifiable; that the published reports of many cases said to be cured by operation are unreliable. For though the operator may have been honest in thinking when he made his report that he had cured his patient—the after-history of the case sometimes showed failure. That the spaying of women for pain alone, and for many of the other supposed causes of trouble for which it is done, and in the miscellaneous way in which it is done, he believed is unwarranted.

Dr. W. H. Parish said that recent experience and literature are teeming with abundant evidence that diseases of the appendages, and more especially of the tubes, are of really the greatest frequency. Most usually the affection is inflammatory in character, and dependent upon catarrh, gonorrhœa, or sepsis. At the time when removal of the appendages is justifiable, sterility has been already established by the disease itself, and such treatment as will obviate that stage of progress of the disease which indicates surgical interference, will also tend to lessen the probability of the establishment of sterility. What is to-day a mild inflammation of an appendage, is liable—it may be very quickly—to become a condition even threatening life, and he is confident that some of the measures to-day directed by many against associated vaginal or uterine inflammation, do frequently aggravate greatly a latent and subsiding salpingitis and ovaritis. Too irritating an application to a gonorrhœal endometrium will certainly convert a quiescent inflammation of the tubes into a pus-forming salpingitis. The same is true in reference to applications made in other forms of endometritis. Gonorrhœa is the most important cause of dangerous salpingitis. The German writers pronounce the catarrhal form of most frequent occurrence, but they find this form most common in prostitutes, and we are most likely to assume, and correctly, that the disease in the prostitute is of gonorrhœal origin.

Hemato-salpinx often endangers life, inasmuch as rupture of a tube containing such altered blood as is found in that affection may originate fatal peritonitis. Now one of the causes of hemato-salpinx is stenosis by narrowing or by flexion of the cervical canal—securing the patulency of that canal may permit the tube to empty itself gradually into the uterus, just as it does after opening up the vagina or uterus in hematomatra or hematocolpus. The inflammatory cases of tubal and ovarian disease are divisible into three groups: one of mild character, on which probably no one would operate for removal; another group, in which the accumulation of pus is so large, and the symptoms so grave that, probably, all operators would agree as to the necessity for removal; and then there is an intermediate group, in which surgical opinion would be at variance as to the propriety of removal. In this group the tubes and ovaries are in a condition of more or less subacute or chronic inflammation, with extensive adhesions, and probably some cystic degeneration. Physical examination does not always in these cases clear up the indications. The environments of the patient, the symptoms and the progress of the case after prolonged judicious treatment, must as yet decide the question.

When, after removal of the inflamed appendages, the relief is not complete, or it may be there is no relief, the explanation is to be looked for often in the incomplete character of the removal—a portion of the tube, especially the uterine portion, or a portion of the ovary has been left, and this becomes the focus of other trouble.

DR. E. L. DUER said that Dr. Kelly has emphasized for us the advantage of the educated touch. Dr. Coe, of the Woman's Hospital, of New York, states that but one-fifth of the ovaries removed are diseased. Pain is such a prominent symptom that it can hardly be called a neurotic manifestation. It is often due to adhesions or to pressure, excepting in cases of gonorrhœal origin, or pus-containing tubes. This question has resolved itself into one of environment. The poor woman who must keep up and at her work, has no relief but by the knife. The rich woman who can be cared for with rest and favorable surroundings, may be relieved, sometimes, for example, by the patient and persistent stretching of adhesions and restoring the circulation of surrounding parts.

DR. SINKLER said that the operation of removal of the ovaries is of great interest to neurologists, because many of the cases of hysteria and nervous prostration which came under their care, are connected with pelvic pain or dysmenorrhœa. Besides Charcot's observations in hystero-epilepsy, relieving the paroxysm by pressure over the ovaries would seem to indicate that in such cases a cure might be expected from removal of the ovaries. The result of the operation, however, although satisfactory in some, is disappointing in a great many cases of this character. He had under his care quite a number of patients in whom the ovaries had been removed for hysteria, neurasthenia, pelvic neuralgias, etc. One case, about twenty-three years of age, an extreme case of hysteria and a persistent masturbator, was under his charge at the Orthopœdic Hospital and Infirmary for Nervous Diseases. After seven months, being unimproved in every respect, she was discharged, and was taken by her friends to another hospital, where her ovaries were removed. After a few months she again came under his care, and he found her in as bad a condition as ever. The hysteria was as marked and she masturbated very often. She did not improve in his hands, and he had recently heard of her after an interval of nearly three years, in a worse state than ever before.

Another case is a lady of forty-two years, who, three years ago, had the ovaries removed for dysmenorrhœa, pelvic distress, and general neurasthenia. After a course of rest treatment she has improved greatly; but it is an interesting fact that she still has attacks in which she says there is a sensation of uterine contraction and pressure, just as there was before the operation.

In conclusion, while he would hesitate to recommend removal of the ovaries for the relief of pelvic pain alone, he did not question that there are many cases of hystero-epilepsy and extreme neurasthenia dependent upon violent and prolonged dysmenorrhœa or ovarian pain, in which the operation is not only justifiable, but is decidedly indicated.

DR. CHAS. K. MILLS said that the ground taken by Dr. Kelly can scarcely be attacked if, as he understood him, operation should be only undertaken in the first place, when local disease can be clearly made out, and, in the second place, such disease can nearly always be recognized by proper methods of examination. Certainly, however, in very many cases of pelvic pain, no disease of the ovaries, tubes, or uterus can be recognized, or, indeed, is present. We have true neuralgias of these organs as we may have of any viscus. Before too much significance be given to the ovaralgia of Charcot, it should be recalled that even in male hysteria, pain in one or the other iliac region has been met with in a number of reported cases. As to the view expressed that operation is sometimes called for when hystero-epileptic and other morbid phenomena are exhibited at or near the menstrual period, we should hesitate in accepting this dictum. All nervous symptoms are likely to be aggravated or excited in neurotic women at the menstrual period. In the *American System of Practical Medicine* he had reported two cases of hystero-epilepsy in which the operation of oöphorectomy was performed. In one of these cases clitoridectomy was also performed. The hystero-epilepsy was not cured in either case. His conclusions are given in this work as follows: "With reference to oöphorectomy for hystero-epilepsy or any form of grave hysteria it may be concluded: 1. It is only rarely justifiable; 2. It is not justifiable in the case of girls who have not menstruated; 3. When disease of the ovaries can be clearly made out by local objective signs, it is sometimes justifiable; 4. It is justifiable in some cases with violent nymphomania; 5. The operation is frequently performed without due consideration, and the statistics of the operation are peculiarly unreliable."

We have few reliable statistics with reference to the performance of pelvic operations for the relief of insanity. In these days, when operations are talked about in every house and almost on every corner, cases of ovarian monomania are likely to be met, cases in which women are determined to be operated upon whether or not; some of these cases are undoubtedly like those of sexual hypochondria or monomania in man, in some of which self-castration is performed. In the wards of the Insane Department of the Philadelphia Hospital is now a patient who has removed both testicles by successive operations, under the influence of such a monomania. Operation upon the ovaries or tubes, or both, in cases of insanity should be restricted to those cases in which either local disease of long standing can be made out, or in which

the outbreak of insanity can be clearly traced to disease or impaired function of these organs.

DR. KELLY said that the cases cited by Dr. Sinkler and Dr. Mills had a direct bearing upon his remarks, and show how important it is that the gynecologist should frequently seek the counsel of the neurologist. Extensive follicular degeneration of the ovaries never *per se*, requires operation, but this is often made necessary by the associated symptoms. All his cases have been benefited; while several continue to suffer from pelvic pain, they are entirely freed from the menstrual exacerbations; most have been raised up from chronic invalidism to perfect health, one attaining this not earlier than a year after the operation. In a case of epilepsy with most marked menstrual exacerbations and severe ovarian pain, the epileptic attacks continue, but she is free from pain, and Dr. Kerlin, under whose charge she now is, considers her improved.

DR. W. W. KEEN reported a

SUCCESSFUL CYSTOTOMY AFTER FAILURE OF SUCTION TO REMOVE A PIECE OF A CATHETER FROM THE BLADDER.

The recent suggestion of Dr. De Forest Willard (THE MEDICAL NEWS, November 26, 1887) and Reginald Harrison (*Lancet*, Oct. 29, 1887), to extract foreign bodies from the bladder by the rubber bulb and evacuator of Bigelow's litholapaxy instrument, makes a valuable addition to our surgical resources in these troublesome cases, and is his especial reason for bringing to your attention the following case. The failure of the method in this particular instance was due to special reasons.

J. W., a healthy man, aged seventy-five years, living in Elkton, Md., had suffered for a considerable time with recurring retention of urine, and cystitis following an enlarged prostate. Dr. Charles M. Ellis, his attending surgeon, very wisely taught him the use of the catheter, which he has employed daily for some months. The Nélaton catheter (No. 22 French), which he has employed, having lost its rigidity, he whittled a pine stick to the necessary size, and sought, by means of this, to introduce it into the bladder, November 7, 1887. In the attempt the catheter broke, and a piece, subsequently ascertained to be 4½ inches long, broke off and passed into the bladder. Severe pain and retention followed immediately, and persisted until after he operated upon him.

Three days after the accident he made repeated unsuccessful efforts at extraction with forceps and lithotrites but was not even able to detect the fragment.

On November 11th and 13th he attempted to remove it by suction with Bigelow's evacuator. On the last occasion Dr. Willard kindly helped him personally. They repeatedly filled the bladder with warm boiled water, being careful to keep the extremity of the evacuating tube just at the vesical extremity of the urethra, but suction had no effect in engaging the fragment. This was amply explained later by finding that it lay crosswise, and was so long that both ends were held fixed by the walls of the bladder, while the relative rigidity of the short fragment prevented any possibility of its being brought to the opening of the evacuating tube, though they sought for it through the tube by Dr. Willard's forceps. An evacuating tube with a lateral eye gave no better results than one with an opening at the end. He also used a rectal bulb filled with seven ounces of warm water, but all to no purpose.

After debating between suprapubic and lateral cystotomy, he decided upon the latter, in consequence of the observation of Harrison and others, that the prostate sometimes shrinks after perineal cystotomy, when a tube is retained in place for some time. Accordingly he did left lateral cystotomy with a staff. With the ordinary lithotomy forceps he easily seized the fragment by the middle, removed it, and introduced a rubber drainage tube with a flange, by which it was easily retained in place by tapes. The patient's temperature never rose above 99°, and in six days he went home, with instructions to retain the tube in place for two months, and then to remove it and allow the opening to heal. By this means he hoped to be able to avoid the necessity for the subsequent daily use of the catheter.

December 5th, after nearly five weeks retention of the drainage tube in the bladder he found that, owing to his feebleness, want of care and cleanliness, the tube was proving a source of irritation and slight suppuration. Accordingly, December 10th, he removed the tube. In three days the wound closed sufficiently to cause him to void his urine by the urethra, and he was no longer obliged to rise at night to relieve the bladder. The prostate has shrunk to some extent, so that he no longer needs to use a catheter. Whether this will be permanent, or is only temporary, time alone will determine.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, December 19, 1887.

THE PRESIDENT, JOHN SHRADY, M.D., IN THE CHAIR.

DR. J. LEWIS SMITH read a paper on

PRESENT OPINIONS REGARDING THE PATHOLOGY AND TREATMENT OF DIPHTHERIA.

No disease in modern times, he said, has attracted more attention than diphtheria, since it is highly contagious and very fatal, is permanently established in many of the larger cities in both hemispheres, and occurs every year epidemically in numerous rural localities. The results of the investigations in regard to the etiology of the disease have tended to establish its microbic origin, but the microbe which is the specific principle of diphtheria is not clearly ascertained. Loeffler, one of the most prominent authorities on the subject, found that every diphtheritic patch contained many species of bacteria, which have been cultivated; but, as they have not been isolated, the specific germ of the disease has not been determined. Another microbe, obtained by Loeffler, and described by Klebs in 1883, merits special attention. In some typical cases of diphtheria, it is true, Loeffler has been unable to find the bacillus, but he suggested that it might possibly have died and been eliminated before death of the patient. The bacilli were found in the exudate in thirteen cases of diphtheria, and cultures to the twenty-fifth generation inoculated in guinea-pigs and birds produced a whitish exudation at the point of inoculation. The researches of Loeffler and Cheyne lend support to the views expressed by Wood and Formad in their able report made to the United States Board of Health in 1882, who arrived at the conclusion

that the two organisms *micrococcus opticus* and *micrococcus diphtheriticus* are specifically one, and that "diphtheria is a septic sore throat, or is simply what was called a century ago putrid sore throat, with or without a secondary constitutional septicæmia."

That the bacillus, said Dr. Smith, is, therefore, the causative agent of diphtheria is rendered probable, and that systemic infection by the diphtheritic poison is not produced directly by the entrance of the microbe into the circulation, but by ptomaines which have sprung into existence through the agency of the microbe, is also the opinion of some of the highest authorities in bacteriology. It is seen that the investigations referred to lend support to the theory that diphtheria is primarily a local malady, and that in certain mild cases it never becomes constitutional, or is constitutional in a very feeble degree. Nevertheless, those who believed that diphtheria was previously constitutional based their opinions on facts that lent strong support to their theory, such as the incubation period of six or seven days in certain cases, the early occurrence of nephritis, even in twenty-four hours in malignant cases, and the existence of very severe and often fatal nephritis in certain cases where the disease of the mucous membrane had been so trivial as to be scarcely appreciable. The mooted subject, whether diphtheria is primarily local, or is primarily constitutional with local manifestations, or whether its nature in this respect varies in different instances, must, therefore, be considered as still undetermined.

As to the propagation of diphtheria the statistics of Professor C. W. Earle, of Chicago, showed that the disease is as severe and fatal in salubrious localities in the newly settled and mountainous States and territories of the Northwest, where it happened to be introduced, as in the foul air of large cities; though dampness and decomposing animal and vegetable substances in rural localities, as in cities, increase the prevalence of the disease. His statistics also showed that diphtheria may be communicated long distances by railways, and probably by merchandise, and they demonstrate its extreme contagiousness from person to person. In the cities there is abundant and melancholy proof of the causative relation of foul air, whether arising from the sewers or stagnant filth, to diphtheria, and Dr. Sternberg, in his recent valuable Lomb Prize Essay, had stated the opinion (which seemed to be borne out by observations relating to the etiology of diphtheria), that the diphtheritic germ, once deposited in damp and foul places, is probably propagated independently of the sick. Thus, in New York City prior to 1850, although foul sewers and insanitary conditions existed, there was no diphtheria; but in the decade following 1850 diphtheria was introduced, its germ made its way into the sewers, where in the filth underground it found a nidus for its propagation, and now wherever sewer gas escapes into the domiciles of this city it is laden with the germs of this disease. The amazing vitality and power of propagation of the diphtheritic germ are apparent when we reflect that it has permanently infected the filthy flowing currents of the sewers in every part of a great city, sewers which, in their ramifications, extend hundreds of miles. It is simply by exposure of children to the sewer gas, carrying with it the diphtheritic germ, which emanates from this widely extending underground culture-bed, and to walking cases of diphtheria, so mild that there is little or no complaint of the throat, or impairment of the general health, that the disease is so prevalent. In Dr. Smith's opinion the germ of diphtheria is of such a nature, and quickly becomes so established in a sewered city, that it can never be "stamped out," as cholera or yellow fever may be, by the active measures of health boards or by legislative enactments, although they may do much in the way of protection.

Having referred in detail to the differential diagnosis of diphtheria, and urged the advisability of enforcing the same precautionary measures in all doubtful cases, as in undoubted diphtheritic disease, Dr. Smith spoke of the area of contagiousness in diphtheria. Dr. Lancry, he said, had cited cases to show that this area is small, being limited to a few feet. Dumas stated that in a school the boys and girls in the same hall were separated by an open space a few yards wide. Diphtheria prevailed among the girls, but did not affect the boys. Other instances were also cited showing that the area of contagiousness, like that of scarlet fever, is within narrow limits, and is, therefore, unlike that of pertussis and measles. The latter diseases, when they enter a domicile or asylum usually affect all the unprotected children. Dr. A. V. Meigs, of Philadelphia, in his interesting paper published last year, on the mode of propagation of the common infectious diseases of childhood, placed diphtheria with scarlet fever and typhoid fever in one group. Diseases in this group, he said, seem to be more under endemic or local influence than are measles and pertussis; not spreading over wide communities, like the latter, and hence, by strict quarantine and preventive measures, their wide extension is more easily prevented. Those who have carefully studied the infectious diseases in children's institutions and elsewhere, will recognize the truthfulness of this distinction.

In speaking of the preventive treatment of diphtheria, Dr. Smith said that Dumas had recommended iodine as a prophylactic; giving to exposed children, in the course of twenty-four hours, a four ounce mixture, containing 8 drops of tincture of iodine and 10 centigrammes (1.34 grains) of iodide of potassium. The most effective method of preventing diphtheria, however, is the isolation and disinfection of the patients, and the disinfection of the apartments, in addition to preventing the inhalation of noxious gases wherever an outbreak of the disease has occurred. Dr. H. B. Baker, of Lansing, Michigan, has published statistics showing that in 102 attacks of diphtheria, the average number of cases where disinfection and isolation (either one or both) were neglected, was 16, and the average of deaths 3.23; while in 116 outbreaks, in which isolation and disinfection were enforced, the average number of cases per outbreak was 2.86, and of deaths 0.66. These precautionary measures, therefore, prevented 13 cases and 2.57 deaths for each outbreak; or, in the total, 1545 cases and 298 deaths in the year. Dr. Smith alluded incidentally to the possible communication of diphtheria to man from animals, stating that recent investigations go to show that it may be thus communicated from poultry, and especially from pigeons; while birds, both wild and tame, are subject to the disease.

Treatment.—The proper treatment of diphtheria is far from being determined, and a chief reason why there is such a difference of opinion in regard to the value of remedies, is because the disease varies greatly in severity in different localities and at different times. In some epidemics a larger majority recover, whatever the treat-

ment (and even with injurious treatment), while in others a large proportion perish under the best possible remedial measures; so that statistics are misleading as to the value of therapeutic agents. In the year 1882 Dr. Lunin met with the following results from different remedies employed at the hospital of Oldenberg. In the fibrinous form of the disease, the percentage of deaths under the various modes of treatment was as follows:

By turpentine	8.30 per cent.
" resorcin	20.06 "
" bichloride of mercury	30.20 "
" chinoline	31.60 "
" tincture of chloride of iron	32.60 "
" bromine	46.70 "

In the septic form the deaths were as follows:

By tincture of chloride of iron	76.5 per cent.
" turpentine	81.0 "
" bromine	88.9 "
" resorcin	89.5 "
" bichloride of mercury	92.9 "
" chinoline	100.0 "

According to Lunin's observations, therefore, in the fibrinous form, turpentine was the most useful therapeutic agent; but in the phlegmonous and septic form the chloride of iron was the most efficient. The cases of fibrinous diphtheria numbered 142, with 43 deaths; of the phlegmonous and septic form, 122 cases, with 103 deaths. In all the cases treated in the Oldenberg Hospital, aggregating 296, 164 were fatal.

After having spoken of the value of tincture of chloride of iron, as advocated by various writers, Dr. Smith took up the consideration of bichloride of mercury, which he said is at the present time regarded by many physicians as the most efficient agent in the treatment of diphtheria. It is the most active and certain of the germicides employed in medicine, whether used locally or internally, and its use in diphtheria rests upon the fact that it quickly destroys all microörganisms with which it comes in contact, and upon the supposition that in safe medicinal doses it penetrates all parts of the system. Among the other authorities quoted concerning its use was Welcher, who recommended as a gargle or spray a solution of the bichloride, one part to one thousand. It was evident, however, Dr. Smith thought, from the experience of other physicians, that when this agent is employed as a spray in so strong a solution as this, it should be used with very great caution; and this is all the more necessary, of course, when the remedy is at the same time being given internally. Dr. E. N. Oatman, of Nyack, N. Y., had reported that he lost but one patient in twenty-three by the following local treatment: Cotton is firmly wound around the end of a stick about the size of an ordinary lead-pencil; being drawn out as it is wound, and made to project beyond the end. This is dipped into a solution of bichloride of mercury, two grains to the pint (1 : 3840), and "passed into the throat until it touches the posterior wall of the pharynx. It is then instantly withdrawn and burnt." This treatment is repeated hourly, with a new swab each time, until the inflammation begins to subside—usually in forty-eight hours. Dr. Smith thought that the quantity of bichloride which could be safely given in twenty-four hours to children of various ages, is about as follows:

To a child 2 years old.	1/6 grain.
" " 4 "	1/4 "
" " 6 "	1/3 "
" " 10 "	1/2 "

Turpentine has been highly recommended recently by physicians of experience for its prompt action, when used locally as well as internally, in arresting the formation and extension of the pseudo-membrane, and as an antidote to the diphtheritic virus. Dr. Lewentaner had reported that an infant of two years, treated by other remedies, began to have symptoms indicating invasion of the larynx on the fourth day. Tracheotomy was resolved upon; but previous trial was made of pure turpentine in a teaspoonful dose. The result was that the croupiness ceased, the other symptoms improved, and the child recovered without tracheotomy. Delthil, by the alleged success of his fumigation treatment, appeared to be the first to draw attention to the use of turpentine in this disease. His treatment was as follows: A mixture of one kilogramme (2 pounds) of coal tar, 8 tablespoonfuls of turpentine, 8 grammes (2 drachms) of resin of benzoin, and 100 grammes (3½ ounces) of cajaput oil; or a mixture of 200 grammes (7 ounces) of coal tar, 80 grammes (2 ozs. 6 drs.) of turpentine; or, turpentine alone, was constantly burnt in the sick-room. The vapor arising from the burning mixture was tolerated by the patient, and did not give rise to vomiting; while it appeared to aid in arresting the diphtheritic process. Schenke modified Delthil's treatment as follows: A mixture was prepared of 200 grammes (6 ounces) of coal tar and 80 grammes (2 ozs. 6 drs.) of turpentine; and of this 50 grammes (1½ ounce) were vaporized at the bedside four or five times a day, each use of the vapor occupying half an hour. His observations led him to believe that the benefit from this treatment accrued chiefly from the turpentine, and largely from its general effect upon the system. He therefore employed turpentine internally in doses of ten minims to one teaspoonful, given from one to three times daily in milk, sugar, water, or gruel. At the same time he employed it as a spray. He also used alcoholic stimulation; and of 36 cases treated by the turpentine, 31 recovered. Rose, of Hamburg, treated 58 cases of diphtheria with turpentine, with the result of 95 per cent. of recoveries. He gave it three times a day in teaspoonful doses, mixed with spirits of ether (ether, 1 part; alcohol, 3 parts), and also gave a teaspoonful of a two per cent. solution of salicylate of sodium every two hours. He used the turpentine cautiously in anæmic cases and in cases with full heart action. Sigel stated that turpentine, in teaspoonful doses, reduced the temperature in 47 cases, in 14 of which the symptoms were so severe that the question of tracheotomy arose, but was postponed by the beneficial effect of the turpentine. Of the whole number of cases treated by him with turpentine, 87, death occurred in 14.9 per cent., while in those treated by bichloride of mercury, salicylic acid, potassium chlorate, etc., 32.5 per cent. died.

Sodium benzoate is another agent that has attracted considerable attention. Blandel had reported two hundred consecutive cases treated with it, without the loss of a single patient. He gave every hour a teaspoonful of a solution containing fifteen grains of the benzoate to the ounce, together with one-sixth of a grain of sulphide of calcium in solution or granule; and the throat was sponged every half hour with a ten per cent. solution of

the benzoate. At the same time the room was kept constantly filled with steam from a vessel containing carbolic acid, turpentine, and oil of eucalyptus. Dr. I. N. Love recommended the sodium benzoate in five, ten, or fifteen grain doses, and, given in syrup and cinnamon water, the solution was not unpleasant. Letzerich, Graham, Brown, and Sanné, from experiments made on animals, considered this agent as a specific against the virus of diphtheria; while Dumas, who had not derived benefit from it in the actual treatment of the disease, proposed, as had been mentioned, that it should be utilized as a precaution.

Renou had considerable success with the following method of treatment: To water constantly boiling a teaspoonful of an alcoholic solution of carbolic acid, salicylic acid, and benzoic acid is now and then added; so that in twenty-four hours 10 drachms (40 grammes) of carbolic acid, 2 drachms (8 grammes) of salicylic acid, and 4 drachms (16 grammes) of benzoic acid are employed. The quantity may be increased if the size of the room, the age of the patient, or the severity of the attack seem to require it. No local treatment, apart from the inhalation, is resorted to; but constitutional treatment and sustaining measures are employed to the fullest extent. Barbet had used Renou's treatment for three years with much success. In 51 cases thus treated 48 recovered. His method is to place on a petroleum stove an earthen pot full of boiling water, into which is put a tablespoonful of Renou's liquid every two hours for adults, and every three hours for children between the ages of one and ten years.

Dr. Smith spoke in strong condemnation of the use of pilocarpine (which had been highly lauded by some authorities), on account of the disastrous results liable to be produced by it. He said he had seen it cause symptoms resembling those in extreme œdema of the lungs.

In speaking of calomel he quoted the favorable opinions expressed by Drs. George B. Fowler, William H. Daly, H. C. Wood, and others, regarding it; but said that the experience of most physicians in New York who had tried it had been unsatisfactory.

Having referred briefly to the treatment by quinine, and by copaiba and cubebs, he passed on to chlorate of potassium, and having presented the views of various authorities in regard to it, gave the following prescription which has been long and favorably known in New York, and is probably more frequently written, with more variations in its properties, than any other in diphtheria.

℞.—Tinct. ferri chlor.	f℥ij-iij.
Potass. chlorat.	℥j.
Acid. muriat. dilut.	gtt. x.
Syr. simplicis	f℥iv.

Dose, one teaspoonful every one or two hours. The tendency, however, has been in late years to diminish the amount of potassium chlorate, or to omit it altogether, from its known irritating action on the kidneys, which are so prone to inflammation in this disease; and he thought it should probably always be omitted if albumen appeared in the urine.

Dr. Smith mentioned, in passing, the use of bromine and of permanganate of potassium, and the styptic treatment by the local application of Monsel's solution, and then spoke of papayotin in diphtheria. Rossbach had used this agent in a solution of the strength of one to twenty frequently applied to the fauces. In very young children a few minims might be placed on the tongue every five minutes. Dr. A. Jacobi stated that papayotin digests a thousand or two thousand parts (according to others, two hundred parts) of moistened fibrin, while not injurious to the mucous membrane. Dr. Jacobi had at one time lost confidence in its efficiency, but afterward had reason to believe that the specimen employed was impure. More recently he had found the drug to act well, and stated that diphtheritic membranes are dissolved in a few hours, in a few cases after a day only. He employed a mixture of one part of papayotin, two parts of glycerine, and two parts of water.

Dr. Smith spoke favorably also of the solvent action of trypsin, which, like that of lime water (by itself of very feeble solvent power), is increased by being used in conjunction with an alkali. He suggested the following formula for a spray:

℞.—Sodii benzoat.	℥j-ij.
Sodii bicarb.	℥ij-iij.
Trypsin	℥j.
Ol. eucalypti	f℥j.
Liq. calcis	Oj.—M.

DR. C. A. LEALE said that after intubation of the larynx, as well as tracheotomy, one great cause of trouble complained of by operators is the difficulty of feeding the patient. To obviate this drawback he had been in the habit of resorting to a very simple and yet very efficient method of introducing food, which he thought ought to be more generally known. This was by means of a Tiemann flexible rubber, velvet-eyed catheter, No. 8, which can readily be passed through the nose and then down the œsophagus into the stomach even when the tube is in position. Thus, with an ordinary syringe liquid food of any variety can be injected through it at will. This device can also be employed during unconsciousness, in convulsions, etc., and on account of its simplicity and easy application it is desirable that it should be understood by all.

DR. FREDERIC S. DENNIS then read a paper on

SELECTED CASES OF SARCOMA IN BONE, WITH PRESENTATION OF SPECIMENS AND MICROSCOPICAL SECTIONS.

(See page 29.)

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Semi-annual Conversational Meeting.

THE PRESIDENT, F. P. HENRY, M.D., IN THE CHAIR.

DR. W. T. COUNCILMAN, of Baltimore, delivered an address on

SOME FURTHER INVESTIGATIONS ON THE MALARIAL GERM OF LAVARAN.

This organism, first described by Lavaran, has been met with in every case of malarial fever which the speaker has seen. The organism is in high degree polymorphous, and ten tolerably distinct forms may be found in the blood. Some of these evidently represent different stages of development, and the connection between them is obvious. Others present such marked differences in form, that no connection between them can be made out. Some of the forms are only found outside of the red corpuscles, and others are found free in the blood.

The forms described are: 1, non-pigmented, small, amœba-like bodies inside the red corpuscles; 2, pigmented bodies, larger than No. 1, also in the red corpuscles; 3, pigmented bodies about the size of red corpuscles; 4, segmenting forms of the No. 3 body; 5, small hyaline bodies, which are formed by this segmentation; 6, a crescent-shaped body with pigment in the centre, the horns of the crescent being often connected by a fine line; 7, round or oval bodies, which differ from No. 6 in shape only; 8, a pigmented body provided with numerous long, actively moving flagellæ; 9, actively moving free flagellæ, which are evidently derived from No. 8; 10, a pigmented body with an active undulatory movement of its periphery. The first five forms are found only in intermittent fever, No. 4 only being seen in the blood during the chill period, and its presence is invariably connected with the chill. Nos. 6 and 7 are found in cases of malarial cachexia.

The most interesting forms, and about whose parasitic nature there can be no doubt, are the bodies Nos. 8 and 9. These are generally absent in blood taken from the finger, but they may be found in any type of the disease. They are the only forms of the organism whose presence in the blood is not associated with a special type of the disease. They were found, however, in 15 out of the 20 cases in which the blood of the spleen was examined. Of these 20 cases, 12 were cases of malarial cachexia and 8 of intermittent fever. In the 12 they were found ten times, and in the 8 cases of intermittent five times. From this it seems probable that Lavaran was right in considering the flagellate organism the most important form of the parasite.

The influence of quinine on the intracorpuscular forms of the parasite is most marked. Doses of 15 grains t. i. d. for two days in succession were found sufficient to cause them to disappear. The effects of the quinine were not so apparent in the other forms. The crescents were apparently not diminished in number in one individual after he had taken 45 grains of quinine daily for seven days, and 60 grains daily for four days.

Dr. Wm. Osler said the thought which had struck him most forcibly, in looking over this subject, was the almost perfect unanimity which has prevailed among the different observers as to the appearance of these organisms. With the sole exception of the segmented form (No. 4), Lavaran and the early observers had described them all. His own observations, since the communication he had presented to the Society last year, had been somewhat limited. He had, however, made a series of observations upon the blood of fishes and birds, since it had been stated that bodies resembling Nos. 1, 2, and 3 had been found in the blood of carp and some waterfowl. Prof. Baird had offered him facilities for this work at Wood's Holl, and had kindly furnished him with forty-five carp. He had failed to detect any such organisms in the blood of these. In the blood of a goose sent him from Ontario he had found one or two pigmented bodies. It had been stated by Dr. McCallum, who sent him the goose, that the bird had malaria. However, the bodies were not numerous, nor was the temperature of the goose elevated; nor, so far as he could make out, had it chills.

Dr. Councilman had not figured one body which is very peculiar indeed, namely a solid body in the centre of a clear space. It stains like a microörganism, varies in size, and, although the body itself does not change in form, yet there are sometimes changes in outline in the clear space surrounding it—they were somewhat abundant in one case only. One other point with regard to the clear bodies (No. 1), in five or six instances he had seen such bodies pass out from the corpuscle, remaining out and undergoing no further change of form. He was not altogether prepared to say what is the relationship of these bodies to the other bodies described. It has been claimed that similar changes can be obtained by special methods of staining the blood. The most important question is first to determine the relationship of the hyaline to the pigmented bodies, and the possibility that the hyaline may not be directly associated with them.

He was convinced that the pigmented and segmented bodies are merely different stages. He could fully confirm what Dr. Councilman said with regard to the crescents. They are most peculiar and interesting bodies, occurring in the chronic cases and in those in which there had been no chills. Three weeks ago he had lectured on a case as one of mild typhoid fever; it had lasted eight or ten days with constant fever, up in the evening, down in the morning, slight enlargement of the spleen, no spots. His resident examined the blood and found what he thought were crescents. The case got rapidly better, left the hospital, and returned in a few days with a distinct chill, with crescents in the blood and a well-marked remittent fever. The motile forms he had not seen nearly so frequently as Dr. Councilman; though he had not examined the blood from the spleen they had been present in eight or ten cases. Nor had he seen free filaments nearly so often; when he wrote his paper he had not seen them at all. Since then he had watched the process of separation. It is out of the question to suppose that the crescents or motile forms can come from degenerations in the stroma of the corpuscle, but that the hyaline forms result from such changes is not altogether improbable, and further investigations are necessary to determine this point.

Dr. J. P. C. Griffith called attention to the diagnostic value of these organisms, and instanced a case, where from the indefinite history and symptoms, he was unable to make a diagnosis until after an examination of the blood, when a short course of treatment resulted in a cure.

Dr. H. C. Wood said that no one seemed to have made any connection between the crescents and the amœboid forms, they seem to differ in that these are destroyed by quinine, those are not affected. We know that malarial cachexia is cured by quinine, arsenic, and iron. If these remedies have no effect on the crescents, what connection have these bodies with malaria, and what becomes of them, do they eventually disappear?

Dr. Formad asked whether these organisms are the same as the bodies described by Hütter some twenty years ago.

Dr. Councilman said, in concluding, that Hütter described moving bodies attacking the red corpuscles, existing in all fevers and apparently almost everywhere else. These observations had never been confirmed. The point raised by Dr. Wood had always puzzled him, and for a long time he had tried to reconcile himself to a belief in two distinct diseases, but this he could not do, as always, as the other forms disappear, the crescents appear. He had never seen the crescents unless with a

history of previous chills. He was not altogether prepared to say that quinine had no effect on the crescents, though in several cases he had given it in large doses with no results. Still in some cases they do seem to disappear. He thought with Dr. Osler that the crescents could not be possibly produced by changes in the stroma of the corpuscles, though some of the other forms might.

NEWS ITEMS.

The Annual Meeting of the Kings County Medical Association, Brooklyn, N. Y., was held January 3d. The election of officers took place with the following result:

President.—E. R. Squibb, M.D.

Vice-President.—T. M. Rochester, M.D.

Secretaries.—R. M. Wyckoff, M.D., and J. A. Jenkins, M.D.

Treasurer.—J. R. Vanderveer, M.D.

Two papers by Drs. McCollum and Rochester were read upon "Fever," and the debate was closed by Dr. Austin Flint, of New York City, who was present by invitation. The attendance was large.

Alumni Association of the Woman's Hospital in the State of New York, held its third annual meeting at the New York Academy of Medicine, January 13, 1888.

Appointment.—Dr. Charles H. May has been appointed Visiting Ophthalmic and Aural Surgeon to the Randall's Island Hospital, New York.

The Cremation of Hospital Garbage.—If the Chicago city crematory for garbage proves successful, Cook County Hospital will erect a similar one for hospital use.

The Spontaneous Explosion of Chlorate of Potassium burst the jar containing it, and set fire recently to a chemist's shop in Barnstaple, England.

The First Recorded Case, in America, of Fatal Œdema of the Larynx, was that of General Washington, who was treated in accordance with the antiphlogistic methods of his time. No local treatment, beyond the inhalation of the vapor of vinegar and water, was employed.

Dr. Asa Gray, the eminent botanist of Harvard University, has recently suffered an attack of apoplexy. He is aged seventy-seven.

A Statue to Von Langenbeck.—At a recent session of the Berlin Medical Society the proposal to erect a statue to the late Professor was favorably discussed, and it was determined to enlist the coöperation of the Congress of German Surgeons, to meet in the coming spring.

Honors to Professors Senator and Hahn, at Berlin.—These well-known members of the Berlin faculty have been given the additional titles of Confidential or Court Advisers, a recognition by the government of their distinguished services.

A Banquet to Péan.—To celebrate his election to the Paris Academy of Medicine, a banquet was recently given to this distinguished surgeon, at which the leading surgeons of Paris congratulated him on his continued success.

Recent Statistics from the Pasteur Institute, Paris.—During the month of October, 1887, 144 persons were treated at the Pasteur Institute, in Paris.

Of these 69 had been bitten by animals proven to be rabid; 96 were bitten by animals said by veterinarians to be rabid; 16 were bitten by suspected animals. Of these patients one has died from hydrophobia; one from another cause.—*Le Bulletin Médical.*

A Physician Convicted of Murder.—Dr. Philip Cross, a retired Surgeon-major, and a licentiate of the Royal College of Surgeons, Ireland, was recently convicted of the murder of his wife, by the administration of arsenic.

Diphtheria in a Dissecting-room.—Some little excitement has been caused in Lyons by the death of a medical student from diphtheria, which, according to the newspapers, he contracted from a subject he had been engaged in dissecting. To this assertion the dean of the faculty wrote a distinct denial, stating that the bodies of patients dead of diphtheria are never sent to the dissecting-room. This, however, did not satisfy everybody, for a rejoinder appeared, signed "A group of *externes*," declaring that the child whose body had been dissected had died of croup. According to *La Province Médicale*, the cause of death was meningitis. Though the practitioner who sent the case to the hospital had diagnosed it as one of diphtheria, the house physician had been unable to find any evidence of diphtheria, and the little patient died the same night that it was admitted. Even if the child had had diphtheria, *La Province Médicale* thinks it is extremely doubtful whether the theory of infection could be maintained, for it is not by any means certain that dead diphtheritic membrane can convey infection, especially after the lapse of eight or nine days, which was the period that had intervened between death and dissection. In addition to this, the unfortunate student had not touched the thorax or throat, having been engaged merely with the brain.—*Lancet,* December 17, 1887.

A French Prize of $2000 has been divided among four Paris physicians for essays upon the "Treatment of Strictures of the Urethra." The essays presented were of such equal merit that no one could be selected for the entire sum.

Lead Poisoning in Modern Industries.—GAUTIER has recently presented to the Paris Council of Public Hygiene a report upon cases of lead poisoning in the Department of the Seine. He has reported at intervals of three years; and for 1884–86 he finds a yearly average of 239 cases, which is a diminution of nearly fifty per cent. as compared with the three years preceding. He ascribes this change to hygienic measures enforced in manufactories, and especially to the discontinuing of the use of a brand of white lead, known as "Clichy white lead," which had proven very disastrous to a number of workingmen. The mortality is greatest among painters, and all who have to do with colors, 19 deaths among 481 cases having occurred in three years. This is caused by the persistent use of lead "whites" when zinc salts could be substituted. Gautier hopes to bring about Government control of this

matter which will oblige manufacturers and railways to abstain from handling lead colors unless mixed with oil, powdered white lead being especially dangerous.

Surburban Hospitals for Contagious Diseases.—Four large hospitals are projected in the vicinity of Paris, two for patients suffering from variola, one for diphtheritics, and one for patients with measles.

The Secularization of Paris Hospitals.—By a recent decision of the Council of Public Assistance the Charité will be deprived of its Sisters of Charity during January, 1888, and their places will be filled by non-religious nurses. The Saint-Louis and l'Hôtel-Dieu will be then the only hospitals in Paris still in charge of Sisters of Charity.

The Advantages of the Inspection of Plumbing by Health Departments.—The *Sanitary Engineer* of December 3, 1887, reports eleven instances of the arrest and conviction of plumbers by the New York Health Department, for defective plumbing. In many instances joints were found stuffed with oakum, or plastered over with a mere film of lead, when these joints were in localities not readily accessible. These arrests and convictions occurred within a few weeks, and give an idea of the constant need for the exercise of municipal authority to secure proper hygiene.

The Construction of Theatres.—The *Lancet* of December 17, 1887, considers it a hopeful sign that the Royal Institute of British Architects has devoted an evening to the discussion of the important subject of the construction of theatres. The construction of theatres must be similar in principle to that of all buildings devoted to large public gatherings, and, as the right of public meeting is just now much exercised by the British public, the proper construction of the rooms in which these meetings are held is of paramount importance from the treble point of view of convenience, health, and safety. Mr. Ralph Nevill, who furnished the paper upon which the subsequent discussion was based, seems to have given much thought to his subject, and many of the points upon which he touched were treated with marked ability. As far as the question of convenience is concerned, Mr. Nevill rightly insisted that the triangular form, with the stage at the apex, is the best, as affording an uninterrupted view to each member of the audience. The little matter of placing the seats in the stalls alternately, so that the persons in the back row can see between those in the row in front, is from the point of view of comfort most important. The remarks as to the dangers of long straight staircases were certainly true, and it should be the aim of architects to lessen the length of staircases as much as possible. It is probable that in case of panic from fire there is less danger in ascending an easy gradient than in descending. The importance of this point is very great, but we do not notice that Mr. Nevill touched upon it in the course of his paper. We are glad to see that Mr. Nevill recognizes the fact that, although the electric light does not foul the air of the theatre to the same extent as gas, it does not assist in the ventilation as the latter illuminant can be made to do. The admission of fresh air and the outlet of foul air, are, after all, the most important points in the construction of theatres, and we are convinced that the draughts, which are the chief characteristics of the modern theatre, are certainly due to the fact that architects do not attack this point with sufficient courage, and the air not being admitted in sufficient quantity in the right places, it must rush through the wrong ones and thus cause draughts.

Dr. Arthur Farre, F.R.S.—The death of Dr. Farre, Professor of Obstetrics in King's College, Physician-Extraordinary to the Queen, and Physician-Accoucheur to their Royal Highnesses the Princess of Wales, Princess Christian, and the Duchess of Edinburgh, is announced, at the age of seventy-six years. He had held offices of distinction in the Royal College of Physicians, and was the author of a well-known work on *The Anatomy of the Uterus and its Appendages.*

Professor Balfour Stewart. the distinguished English physicist, died recently, aged fifty-nine years. He had been Director of the Kew Observatory, and was awarded the Rumford medal of the Royal Society for his discovery of the law of equality between the absorption and radiative powers of bodies.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM JANUARY 1 TO JANUARY 9, 1888.

Cleary, P. J., *Major and Surgeon.*—Granted leave of absence for one month.—*S. O. 138, Department of Arizona*, December 25, 1887.

Ebert, R. G., *Captain and Assistant Surgeon.*—Ordered from Custer, Montana, to Fort Pembina, Dakota Territory.—*S. O. 301, A. G. O.*, December 30, 1887.

Appel, A. H., *Captain and Assistant Surgeon.*—Granted leave of absence for twenty days.—*S. O. 1, Department of Missouri*, January 3, 1888.

Ewings, C. B., *First Lieutenant and Assistant Surgeon.*—Granted one months leave.—*S. O. 137, Department of Missouri*, December 27, 1887.

Banister, William B., *First Lieutenant and Assistant Surgeon.*—Ordered from Fort Lowell, Arizona, to Fort Wingate, New Mexico.—*S. O. 3, A. G. O.*, January 5, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING JANUARY 7, 1888.

Murray, R. D., *Surgeon.*—On being relieved at Ship Island, Miss., to proceed to Key West, Fla., and assume charge of the Service, January 4, 1888.

Devan, S. C., *Passed Assistant Surgeon.*—Relieved from duty at Port Townsend, Washington Territory, to assume charge of Sapelo Quarantine, January 5, 1888.

Glennan, A. H., *Passed Assistant Surgeon.*—Relieved from duty at Key West, Fla., to assume charge of the service at Port Townsend, Washington Territory, January 5, 1888.

Covington, P. M., *Assistant Surgeon.*—Promoted and appointed Passed Assistant Surgeon from January 20, 1888, January 7, 1888.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

SUICIDE IN ITS RELATION TO INSANITY.

An Address delivered before the Medical Jurisprudence Society of Philadelphia, December 13, 1887.

BY JOHN J. REESE, M.D.,

PROFESSOR OF MEDICAL JURISPRUDENCE AND TOXICOLOGY IN THE UNIVERSITY OF PENNSYLVANIA.

THE alarming increase of cases of suicide within the past few years, especially in this country, calls for the serious consideration not only of the philanthropist, but also of the medical jurist. Indeed, the medico-legal considerations connected with this subject are not only interesting to the student of legal medicine, but they involve questions of the deepest significance, which not infrequently claim the attention of our courts of law, and enlist the best talent of both the legal and medical professions.

This subject of suicide presents numerous phases for examination which are interesting and instructive for us as medical jurists; but I propose to limit myself to the discussion of a single one of them, viz., the relation of suicide to insanity in its medico-legal aspects. Does, or does not, the act of self-destruction always presuppose the existence of insanity? Or, in other words, is suicide to be regarded always as evidence of a deranged mind? The settlement of this question touches some of the most vital interests of society, and according as the verdict rendered is yea or nay, in any particular case of suicide, will be the feeling of the survivors that the act of the unhappy victim was an irresponsible one, and therefore guiltless, or that it was truly a case of voluntary, conscious self-murder, with all its appalling guilt and tremendous consequences!

I have no doubt that in the average mind, especially the unprofessional mind, there is a strong conviction that suicide is very generally—if not always—the result of an insane impulse; that no person in his, or her, sober senses could possibly commit such a terrible act as self-destruction; and therefore that the act itself is conclusive evidence of insanity. "This doctrine," as has been remarked by another, "popularly finds expression in the verdicts of coroner's juries, who, desirous of respecting the feeling of surviving relatives and friends, usually return the stereotyped verdict of 'suicide while laboring under temporary aberration of mind.'" Indeed, are we not told on the highest authority that "All that a man hath will he give for his life?" Can it then be supposed that a human being, in a rational state of mind, will voluntarily throw away that which is so precious to him, and rush unbidden into the uncertainties of an unknown world? In a recent discussion on this subject before the New York Medico-legal Society, one of the members, a medical gentleman, maintained very decidedly that suicide is a *disease*, and should, therefore, be regarded as irresponsible.

It will be my purpose in this paper to show that while in many, possibly in the majority of cases, the act of suicide may be traceable to a deranged intellect, still there are instances, not a few, which cannot be explained in this manner; but which must be attributed simply to the firm, deliberate purpose and intention of the individual,—the mind acting throughout in a perfectly rational, intelligent manner, and the will influenced by motives sufficiently cogent to impel to the fatal act.

I would ask your attention to two distinct propositions: First, that suicide is, unquestionably, very often the direct consequence of insanity; and, secondly, that suicide is also frequently to be ascribed to the calm, deliberate determination of a perfectly sane individual. These two propositions, although seeming contradictory and opposite, are not so in reality, as will be seen as we view the subject from different standpoints.

The first of these propositions, viz., that suicide is often directly the result of insanity, is so palpable as scarcely to require proof. Every practitioner of medicine can testify to multitudes of such unhappy cases, the result either of the delirium of acute fever or cerebral inflammation, or of chronic morbid melancholia. Indeed, he well knows that in the last named variety of insanity, the *suicidal propensity*, as it is called, is a symptom demanding the most unwearied watchfulness on the part of the attendants.

It may be as well to notice here that this "suicidal impulse" sometimes displays itself very suddenly, and without any apparent previous warning; whilst at other times it assumes the form of a delusion or hallucination, which, like an invisible spirit, may haunt the unhappy victim for months or years. A well known striking instance of the former is related by Sir C. Bell: "One of the surgeons of the Middlesex Hospital was in the habit of going every morning to be shaved by a barber in the neighborhood, who was known as a steady, industrious man. One morning, the surgeon was conversing with the barber about an attempt at suicide that had recently occurred; and the surgeon observed that the man had not cut his throat in the right place. The barber then inquired casually where the cut should have been made? The surgeon pointed out on his own neck the situation of the carotid artery. The barber, in a few minutes, retired to the back of his shop, and there cut his throat with the razor with which he had been shaving the surgeon. He had wounded the carotid artery in the place indicated by the surgeon, and died before any assistance could be rendered to him." As is properly remarked by the relator, "although this act was quite sudden and unexpected, it may have been only the final result of a delusion which had long existed, concealed from others in the mind of the man—just as the sight of a weapon has often led to its use for the purposes of suicide."

I do not myself believe that this "suicidal impulse"

ever manifests itself suddenly, and for the first time in a person of a perfectly normal mental calibre—like a flash of lightning out of a clear mid-day sky. I cannot but think that if the history of the individual be carefully traced, there will generally be discovered some evidences of antecedent, latent mental aberration, either inherited or acquired.

As regards those cases of "suicidal impulse" of a more chronic nature, such as are so frequently seen in melancholia, I need only to allude to them here, in passing. Of course, there can be no question about all such cases being directly attributable to insanity.

Let us next examine the second proposition, viz., that suicide is not necessarily evidence of insanity, but that cases do occur, not unfrequently, where the act of self-destruction was the result of a calm, deliberate determination, based on sufficient motives, and executed for a special purpose. And here, let me say a word or two about *motive*, as an important factor in determining any case of alleged insanity. If we desire to form a correct estimate of a certain action or line of conduct, we usually endeavor to ascertain the *motives* which prompted thereto. The *motiveless* character of a particular act is generally regarded as strong evidence of a deficiency of mental capacity; and it is constantly urged by counsel before the jury, as a very strong proof of mental unsoundness on the part of a client, whom he is laboring to defend. Unquestionably, there is much truth in this proposition, as far as it goes; but before assenting to it universally, or unconditionally, we should first set about to discover whether under the *apparent* want of motive, there may not have lain, deep down in concealment from every human eye, and scarcely recognizable by the individual himself, a motive, sufficiently powerful *in that particular person*, to instigate to just such a criminal act as the one for which he is now undergoing trial. Professor Casper justly remarks that we are very apt to be misled in our interpretation of criminal acts, by our false notions about the *apparent* want of motive in the criminal. I beg you to notice this point particularly. "It is undoubtedly true that a motive to any deed may exist for one person, under the power of which he is urged on, which would be wholly inoperative in a hundred other cases. To recognize this, however, the inquirer must in every case place himself in the position of the culprit, and divest himself of his own ideas for the time being." There is great force in these words of Casper. This distinguished authority gives us two illustrations of his meaning, taken from the two extremes of social life. One of them, an utterly depraved character, had run a life-long reckless course, and had committed offences for which he had often been imprisoned. This abandoned man is by chance thrown in company with another tramp, who happens to display before his eyes a trifling sum of money—a few coins. The criminal is seized with the desire of possessing this money, and to gratify this desire he will not scruple to murder his fellow. The other instance is that of a young military officer of high birth, and higher spirit, who, while walking in the public park, among a company of ladies and gentlemen, is suddenly assaulted in the grossest manner by a blow in the face, by some low, abusive fellow. Transported with rage beyond endurance, he draws a pistol, and shoots his assailant dead, or runs him through with his sword.

Now, here we have two criminals, each of whom has committed the terrible crime of homicide; and how are we to interpret these different acts? On their trial, their counsel might probably urge the plea of temporary insanity, based upon the want of sufficient motive for the commission of so grave an offence, under such apparently insufficient inducement. And doubtless, had these two culprits exchanged places, the *motive* actuating each would have changed also, and the result would not have been so tragic. "For," as he remarks, "it need hardly be supposed that the young, educated officer would have been tempted to commit murder merely to obtain possession of a few insignificant coins; nor, on the other hand, that the first-mentioned criminal would have possessed so touchy a sense of honor, as not to be able to cool his wrath, and satisfy it with his fists alone, without deeming it necessary to kill his antagonist."

These illustrations, although pertaining to homicide, are equally applicable to cases of suicide. Let us not, then, be too hasty in ignoring the existence of *motive* in cases of criminal nature, whether of homicide or suicide, even though we ourselves may not be able to fathom that motive in the other, nor indeed even to conceive of its existence. I think I am perfectly safe in assuming that we may regard the presence or absence of motive—of *real* motive—as the pivot, so to speak, on which will hinge the decision as to whether any one particular act of suicide was, or was not, the result of insanity. You will observe, I say, the existence of *real* motive. It is not necessary that it should be such a motive as would influence you or me, *in our present circumstances;* but a motive sufficiently constraining *under the particular circumstance in which the individual was placed in that special crisis of his life.*

To take a very common and familiar illustration: A person in good social position, who has always enjoyed the confidence and respect of the community, has for years been secretly defrauding his employer, or his wards, of large sums of money, until concealment is no longer possible, and the terrible revelation is about to be made of the utter financial ruin of his unsuspecting victims. He foresees the near approach of the crisis which he too well knows must unmask his hypocrisy, and expose him to the just indignation of the world, and drag him down to the felon's doom. Shall he quietly wait for the avenging sword to fall upon his devoted head, or shall he not rather save himself from the dreadful exposure, with all its awful consequences, by a swift but deliberate act of self-destruction? Now try this case by our touchstone of *motive*. Will any one say that there was not motive sufficient here to account for the suicide? There was no hallucination, nor delusion of mind interfering with the man's reasoning processes, or preventing the free exercise of his volition. The motive was based on a reality, on a real estimate of his position and its consequences. Of the two great evils, loss of honor or loss of life, he deliberately chose what he considered the less, and so died by his own hand. Certainly we cannot ascribe such a suicide to insanity! Do any of us believe for a moment, that the anarchists of Chicago, who have so lately met their doom, would not gladly have forestalled their well-merited execution by a dynamite or other suicide, if only the means had been granted them,—as in truth it was in one instance? And in precisely the same category would I place those cases of self-destruction following loss of honor, loss of property, loss of employment, mortified

pride, disappointed love, disappointed ambition, remorse, and other kindred causes. Take away from the wretched ones of earth all belief in the existence of God, and of a future state of retribution, and what, I ask, is to hinder them from putting a speedy end to all their sorrows and disappointments?

I know very well that some will urge that all such individuals have been driven into temporary insanity by their various sorrows, disappointments, losses and afflictions; and that the suicidal act was committed while under this temporary insane delusion. The reply to this apparently valid, though really specious, objection is, that it is "begging the question" to assume the very thing required to be proved. Such a line of argument would equally excuse any, and every act of violence inflicted upon another, upon a similar plea of insanity.

It may not, perhaps, be amiss to fortify this second proposition, that suicide is frequently *not* the result of insanity, by an appeal to history, ancient and modern, sacred and profane. It is well known that in the highest civilization of ancient Greece and Rome, the Stoic and Epicurean philosophy maintained not only the lawfulness of suicide, but openly taught that it was preferable to great pain and disgrace; and in accordance with this universally prevalent doctrine, the wisest and most illustrious men of that age killed themselves, rather than be dishonored, or suffer pain. Thus Zeno, the founder of the Stoics, hanged himself, in his ninety-eighth year, rather than endure the pain and inconvenience of a dislocated joint. The generals, Mithridates, Hannibal, Themistocles, Mark Antony, Brutus and Cassius, all sought a similar death, after being defeated in battle. Demosthenes, Cato of Utica, Seneca and Cleopatra believed in suicide, and practised it.

Sacred history affords us many examples of voluntary self-destruction in the persons of king Saul of Israel; of the mighty Samson; of Ahithophel, king David's trusted counsellor; and of the traitor Judas. No one, for a moment, would think of ascribing any of the above instances of suicide to insanity. Certainly, those concerned, comprising philosophers, statesmen, generals and commoners, were persons of no mean order of intelligence.

In more modern times, there have not been wanting persons of brilliant intellect, though of sceptical belief, who have openly advocated both the lawfulness, and the desirableness of suicide; among whom I may mention Rousseau, Gibbon, Hume, Mme. de Stäel, Montaigne and Montesquieu. However we may condemn the doctrines of these people, we cannot surely ascribe their false opinions to any want of intellect, since we well know that they shone as stars of the first magnitude in the literary and social circles of the age.

Even in our own time, in some of the Oriental countries, the practice of self-immolation still prevails to a certain extent. The custom of the Hindoo widow burning herself upon the funeral-pyre of her husband, I believe still lingers in certain parts of India; and the singular custom of *hari-kari* is scarcely yet abolished in Japan.

The benignant influence of the Christian religion, as it gradually spread over the world, had the effect of working a radical change in the popular sentiment as regards suicide. The old heathenish notion of its lawfulness was abandoned, and the practice came to be regarded as a *crime* of the first magnitude, and to be punished as such by the laws of the country. Indeed, so severe were the penalties annexed to this crime, as visited upon the person, the effects, and even the family of the *felo-de-se*, that a recoil of popular feeling took place against the barbarous and revolting laws of that age; and, as a consequence, the attempt was made, and gradually obtained a foothold, to ascribe such cases to the action of a disordered intellect, so as thus to avoid the imputation of crime.

The laws of the Church at this period were equally severe against the practice of suicide—regarding it as a crime of the highest magnitude, and refusing Christian burial to the bodies, and Christian consolation to the souls, of suicides.

Now, you will observe, that this very fact of suicide being regarded by the laws both of the Church and State as a *crime*, and to be punished accordingly, is a conclusive proof that these laws did not consider it as originating in insanity; otherwise such laws would be most monstrous and inhuman, inasmuch as insanity necessarily precludes all idea of responsibility. In England, scarce half a century has elapsed since the bodies of suicides were denied the right of Christian burial; and up to that same period the old practice still prevailed of burying the body of the suicide at the cross-roads, and thrusting a stake through it, in order to show the public detestation of the crime.

At the present day, this question of "the relation of suicide to insanity" most frequently presents itself in cases of life insurance, where there is a dispute about the payment of the policy to the heirs of the deceased, on the ground of his alleged death by suicide; and it very often occasions no little difficulty to the courts. Until within a few years past, it was the general practice of life insurance companies to insert in their policies a saving clause, exonerating them from payment in case the death of the assured was caused by his own hand; and making no distinction between a sane and an insane suicide. This was manifestly both unjust and unlawful, so far as the *insane* act of self-destruction is concerned; for most certainly, an individual should be held no more responsible for the loss of his life, whether he takes it by his own hand when impelled by the delusions of melancholia, or under the ravings of the delirium of a fever, or of cerebral inflammation, than if he dies from an ordinary disease, or from an accident. If, on the other hand, it can be clearly shown that the assured, after placing enormous amounts of insurance money upon his life, in various offices, and making only one or two payments of the premiums, had put an end to his own life, in a perfectly intelligent manner, and evidently with the intent and design of benefiting others—and especially his own family—pecuniarily, by his death, then the question assumes altogether a different aspect. Neither justice nor equity could plead in his favor, in such a case. Undoubtedly, under such circumstances, the company should be exempted from payment, unless it can be clearly demonstrated that the individual was insane at the time when the act was committed.

I might detail many such cases, of considerable interest, to you, but I will be content with a bare allusion to two instances, both of them of very recent occurrence, and both remarkable for the large amounts of money involved. The one is the celebrated Dwight case, which occurred about two years ago at Binghamton, N. Y., involving several hundred thousand dollars of insurance money, in

various offices. This case has been tried in the different courts, and we now hear that it has been recently compromised. The other case is that of Tyler, of Norwalk, Conn., which occurred within the present year. This man, having spent a fortune in profligate living, applied within the space of six months for an aggregate sum of $400,000 of insurance on his life, having previously announced his intention to effect this large insurance for the benefit of his various creditors, and then to kill himself. By false statements to the offices to which he made application, he succeeded in his design. He then writes to his mother of his intention to take his life; after which, he comes to Philadelphia; from which city he again communicates to a friend his suicidal purpose, under an assumed name; and, finally, he returns to Norwalk, and is found in the morning dead in his bed, from an overdose of morphine, leaving a memorandum upon his table. The majority of the insurance companies, I am informed, are defending their cases in the courts upon various grounds—amongst others, on that of conspiracy between the deceased and the creditors.

In each of the above cases, to which I have made brief allusion, there are certainly very strong reasons to suspect voluntary suicide to have been the true cause of death; and that, too, without the slightest suspicion of insanity on the part of the deceased.

You will notice a most significant fact in these, and in analogous cases, viz., that the insurance on the life of the person had been but lately effected, and usually for a considerable amount, and in various offices; and, further, that only one or two premiums had been paid before the suicidal death occurred.

Now, I do not think that we need be much surprised at such occurrences. Why should not such an individual, pressed down by the burden of some enormous debt, which he has been vainly hoping to pay, (if restrained by no belief in, or dread of, a future judgment)—why, I say, should he *not* embrace the tempting offer to insure his life for an amount which will not only repay his indebtedness, and rescue his name from dishonor, but at the same time save from poverty and want those whom he loves better than himself? Try this case, again, by the touchstone of "motive." Why should not the spirit of self-sacrifice be as dominant in such a one, as in any of the cases that we have just been considering?

To quote the words of another: "The pelican which picks its own bleeding breast to nourish its savage young, has been adopted as the symbol and title of one of the largest life offices of Great Britain; and who shall speak other than reverently of that played-out rake, who took his own life, after liberally insuring it, in order, as he said, to enable his widow to start again with a younger and more vigorous man?" Remember, I beg you, my simple object, in this line of argument, is not to enter a plea for the lawfulness of suicide, but simply to demonstrate that in none of such cases can the plea of insanity be urged as the true cause of the self-destruction.

Remember, moreover, that insanity alone is not by any means an all-sufficient excuse, in the eye of the law, for the commission of suicide, in a life-insurance case; but it must be proved that the suicide was not an *intelligent* act, and that it was produced by an insane impulse or delusion, which it was out of the power of the deceased to resist. The point at issue is—did the assured intend *freely* and *intelligently*, to destroy himself?—*intelligently*, *i. e.*, with his mind at the time unswayed by insane delusion? I pray you to observe the very important distinction between doing a thing *intentionally*, and doing it *intelligently*. The insane man, equally with the sane one, commits the act of self-destruction intentionally or knowingly, with the full purpose in view of terminating his existence; but he does not do it *intelligently*, with his mind in its normal equipoise, and "unswayed by an insane delusion."

A recent writer on this subject, the Hon. O. H. Palmer, of New York, to whom I am indebted for some of the points already noticed, says: "My experience for the past five years in the investigations of cases of suicide, has forced upon my mind the conclusion that but a comparatively small number of suicides, even in this country, is attributable to insanity."

I will close this paper with the mention of a few interesting statistics, connected with the subject of suicide.[1]

It appears that suicide occurs much more frequently among men than women: in England the proportion being about 2½ to 1; and in France about 4 to 1. According to Brierre de Boismont, more than 100,000 Frenchmen have committed suicide since the beginning of the present century; the statistics for the single year 1876 show the number for that year to have been 5567, of whom 4435 were men, and 1132 women. Twenty-nine were men under 16 years; and ninety-eight over 80 years. In both countries, the numbers increased notably with the age. Thus, in France the number under 16 years amounted to one per cent.; between 30 and 40 years, to fourteen per cent.; between 50 and 60 years, to twenty per cent.; and over 60 years, to thirty per cent.

As regards *locality*, in both countries the proportion of suicidal deaths is vastly greater in the cities than in the rural districts. In the Department of the Seine (which includes the city of Paris) they amounted to one-sixth of the whole number.

As respects *occupations*, the statistics of the two countries show a considerable difference. In France, agricultural occupations represent 23 per cent.; laborers and mechanics, 28 per cent.; merchants, property owners and professional men, 12 to 13 per cent.; personal servants, 9 per cent. In England, the mortality from suicide was greatest among soldiers; and was higher among the educated classes than among those exposed to rough, out-of-door pursuits.

As regards the *manner of death*, in both countries hanging appeared to be the favorite method adopted; next come drowning, shooting, and poison. Military and naval men, and members of the legal and clerical professions seem to prefer death by firearms, whilst physicians, dentists, chemists, and photographers appear to select some one of the many poisons with which they are familiar. Women usually show a preference for drowning, or poison.[2]

Finally, as respects the different *causes* leading to suicide: in France, 25 per cent. are set down to illness and physical suffering; 31 per cent. are credited to in-

[1] These have been derived mostly from a paper by Dr. John G. Lee, of this city, published in the Philadelphia Medical Times, June 12, 1886.

[2] The statistics of the 98 suicidal deaths in the city of Philadelphia for the year 1887 indicate a preference for poison. The suicides are, poison, 27; hanging, 23; firearms, 21; the knife, 11 drowning, 7; other modes, 9.

sanity; 15 per cent. to family troubles; 16 per cent. are ascribed to dissipation and misconduct; 11 per cent. were directly traceable to alcoholism; 13 per cent. to financial embarrassment and poverty. In the above statement, it is worthy of note, as appertaining directly to the special subject of the present paper, that only 31 per cent. of the whole number of suicides—less than one-third—are credited to insanity.

TUMORS OF THE CHOROID PLEXUS IN THE NEIGHBORHOOD OF THE FORAMEN OF MONRO.

BY ROBERT T. EDES, M.D.,
OF WASHINGTON, D. C.,
FORMERLY JACKSON PROFESSOR OF CLINICAL MEDICINE IN HARVARD UNIVERSITY.

THE presence in the choroid plexuses of the cerebral ventricles of small, cyst-like bodies in greater or less numbers, with semifluid or gelatinous stroma, and containing minute concretions of phosphate and carbonate of lime, with, not infrequently, cholesterine, is a very familiar fact. When found during the examination of a brain they are usually noted as a matter of routine, but seldom have any clinical significance attached to them. They are probably more frequent in brains which have been subject to frequent congestions, but even this supposition is not well established. Tumors of other kinds are less common, although nearly every variety has been met with.

Any tumor of the choroid plexus, if growing sufficiently large—which, however, these cysts or myxomata rarely do—may of course, like any other tumor of the brain, produce, by its direct pressure, localized symptoms. In a very few instances, however, one of which has given the occasion for this article, one of these usually harmless growths, not of large size, has been found so situated as to give rise to fatal results, not by direct pressure upon the cerebral substance, but from its influence upon the accumulation of fluid in the ventricles, so that we have an acute internal hydrocephalus, to be distinguished, on the one hand, from the ordinary internal hydrocephalus, usually chronic, and either congenital or acquired soon after birth; and, on the other, from ordinary acute hydrocephalus, chiefly external, which means tubercular meningitis. The situation especially adapted to produce this result is in the foramen of Monro, where the choroid plexuses of the two lateral ventricles become continuous with each other through the upper branches of the Y-shaped foramen, and where a small, round tumor may completely occlude the lower branch leading to the third ventricle.

Tumors in other portions of the choroid plexus, however, are apt to be accompanied, in chronic cases, by a certain accumulation of fluid secretion, resulting, according to the situation, from obstruction of the circulation, and in part very possibly from a pathological condition of over-activity of the secreting surfaces of the plexus and the ependyma. There are cases where choroidal tumors in the third ventricle, but somewhat posterior to the locality described, have produced a similar result, in addition to the effects of a direct pressure upon the ganglia underneath (optic thalami and lenticular nuclei). Pressure upon the venæ Galeni running along the roof of the third ventricle has apparently the same results in the production of hydrocephalus as venous obstruction elsewhere has in producing ascites, for example. It is not certain to what extent the choroid plexuses, and in fact the ependyma of the ventricles, are to be looked upon as true secreting structures in normal conditions, though it is clear that, pathologically, they may, like the peritoneum, pleura, or synovial membranes, pour out an excess of fluid.

Two theories, which do not, however, exclude each other, may be suggested to account for a large accumulation of approximately normal fluid in large quantity: first, that the ventricles, including the choroid plexuses—which are evidently, from their structure, fitted to be not only temporary reservoirs of blood, but for straining off some of its fluid and saline constituents—constantly pour out a fluid which passes through the foramen of Monro to the third, through the aqueduct of Sylvius (*iter a tertio ad quartum ventriculum*) to the fourth, and then through the foramen of Magendie to the subarachnoid spaces, where it is brought into connection with the general lymphatic system and absorbed. The existence of this last foramen has been doubted or denied by Kölliker and others, but seems to be established by the researches of Luschka and Key and Retzius. The second theory is that it does not circulate in a constant direction, but is subject to fluctuations in either direction through the passages just named, according to the local variations in the amount of blood contained in the cerebral vessels.

Upon either hypothesis it is easy to see how a tumor in the position described leads to an accumulation of fluid in the two lateral ventricles; on the first, simply obstructing the discharge of secretion, and on the second, acting as a ball-valve to admit an upward flow and prevent its return.

An accumulation of fluid in the lateral ventricles is more peculiarly fitted to produce a general and equalized pressure upon the cerebral hemispheres, while sparing to some extent the cerebellum, mesocephalon, and great ganglia, than almost any other condition, except hemorrhage in the same region acting from within, or a meningeal hemorrhage or inflammation distributed with more than usual even-

ness over the surface; and we can, therefore, look upon it as presenting the purest possible type of cerebral compression.

Schnopfhagen (*Stzber. d. Wiener Akad.*, Bd. 73–74, p. 447) says, that the choroidal cysts are especially frequent from the glomus forward to the foramen of Monro, and that another favorite place is on the under surface of the tela choroidea media—that is, the roof of the third ventricle—corresponding to the venæ internæ cerebri which open into the venæ Galeni.

The following cases are only those where a tumor was situated in the exact region first described—that is, the lower branch of the foramen of Monro, or in the third ventricle a little further back, where, if it be at all closely applied to the walls, the effect is essentially the same in the production of ventricular effusion plus more or less local irritation. I have not added to them the other cases—somewhat more numerous, though by no means common—of tumors situated in one of the lateral or the fourth ventricle, where the symptoms are apt to be of another character, though often including hydrocephalus. These may be found in a paper by Audry, in the *Revue de Médecine*, November, 1860, p. 807.

Of the first set (foraminal) I find only two: one by Förster (*Wurzburger med. Zeitschr.*, 1864, p. 39), and the other reported here for the first time.

Case I.—Girl, aged twenty. Had had headaches for a long time, and attacks of vertigo. She died suddenly of apoplexy. At the autopsy the ventricles were found moderately enlarged, filled with clear water, and a growth in the median line of the choroid plexus which had evidently caused the hydrocephalus. The growth was in the middle ventricle, directly at and in part in the much enlarged foramen of Monro. It was firmly situated in the tissue of the median choroid plexus, which partly entered it and partly spread about it. It was roundish, eight lines by six, well defined, smooth like connective tissue, with mucous, almost fluid substance. There were no other remarkable changes in the body.

Case II.—Mr. B., a man in early middle life was a patient of Dr. Fifield, of Boston, and was seen by the late Professor Ellis, who also made the autopsy and from whose notes and my own recollection I can give the following history: He had generally been very well, though subject to sick headaches, had bilious attacks, but no severe attack of the kind for two years. Had recently been overworked in his business. March 30th he came home saying they didn't know how his head felt, and he should be crazy if he kept on. The next day he returned to business and seemed about as usual. April 1st he went to church, ate heartily of roast veal and walked in the afternoon. At night complained again, had sickness of the stomach, lay on the lounge all the evening. The next day went to town, ate beefsteak for dinner, but about six o'clock came home and threw himself upon the bed with his overcoat on; didn't feel that he could undress. His feet were cold, he was sick all night and vomited.

At half-past seven the next morning he did not seem stupid, but about nine he seemed to be so. He gradually grew heavier until noon, seemed bewildered, soon became perfectly stupid and continued so. At eleven it was noticed that the right pupil was dilated and the left contracted. At one he could be roused by shouting; his arms were closed, resisting extension. About four ounces of urine were drawn and contained no albumen, sp. gr. 1.038, alkaline. Pulse 64, of good character; respiration easy and normal; temperature 101° in the mouth. He died at two. The rapid change at the last was somewhat unexpected.

At the autopsy the convolutions were found dry and flattened. In the lateral ventricles were six ounces of clear serum. In the choroid plexus, and directly in the foramen of Monro was a soft, grayish rounded tumor, partly of gelatinous character, which broke easily and contained many granules and imperfect cells. The dilatation of the ventricles in this case was very remarkable. After the fluid had escaped they retained their size and form and looked as if dug out of a solid substance.

In the second set of cases there are also two, one reported by Dr. J. Stedman (*Boston Medical and Surgical Journal*, 1883, cix. p. 135), and the second by Wallmann (Virchow's *Archiv*, 14, p. 385)

Case III.—An architect, aged twenty-eight. Has never been very robust; while in college was thrown from a horse, but remounted, and rode two miles without difficulty; had no unpleasant after-effects. For the last year has had occasional severe headaches, and once called things by the wrong names. March 3d he appeared well, worked during the day, and dined with a good appetite. At four o'clock the next morning had a severe attack of headache, for which he took thirty drops of laudanum, repeated in an hour. The headache increasing, he was seen by the doctor, who gave four drachms of ether by inhalation, which quieted the patient and gave natural sleep at eleven o'clock. When seen at half-past twelve he was found to be dead, but this had happened so quietly that those in the room did not know it.

The autopsy by Dr. Fitz showed the cerebral substance anæmic and dry. Lateral ventricles distended with a clear, watery fluid, and one-third larger than normal size. A gray gelatinous tumor, the size of a filbert, was found upon the velum interpositum in the median line, behind the fifth ventricle in the region of the anterior commissure, on a level with the junction of the corpora striata and the optic thalami. The tumor was easily removed from its surroundings, and on examination proved to be cystic with gelatinous colloid contents.

Case IV.—A man fifty years old, a drinker, had bad nutrition, a very slow and uncertain gait, dull and slow speech, and diminished intelligence. There were involuntary discharges from the rectum and bladder, this symptom developing rapidly without

known cause. This paretic condition of the sacral plexus increasing, his lower extremities were finally completely paralyzed. There were increasing mental dulness and a final facial erysipelas.

The lateral ventricles were much distended with a watery serous fluid. The lower and middle horns were very roomy. In the right choroid plexus was a soft, yellowish-white, lobulated growth as large as a bean, which was a lipoma. The upper surface of the thalami optici was much flattened and the two thalami optici pressed away from each other. The fornix was more than an inch wide and pushed upward toward the septum ventriculorum in the form of a convex growth. Beneath the fornix was an oval thick-walled bladder, as large as a walnut, 3.2 inches long, 1.6 inches wide, which arose with its posterior end from the median choroid plexus and was connected with the pia by a delicate membrane and also with the membrane-like distended posterior commissure. The rest of the growth was mostly free. The contents were gum-like and a tenacious, fluid, yellowish-brown mass. The base of the third ventricle was thinned and delicate.

By comparing the first three of these four cases, where the lesion was of the simplest possible character, and probably produced little if any effect by its pressure upon the nervous structures, we find that a uniform and general pressure upon the cerebral hemispheres exerted by the accumulation of fluid in their interior, and rendering them anæmic, gives rise to no local paralytic symptoms, and to but little irritation, but to headache, gradually increasing somnolence rather than coma, and rapid and quiet death.

These symptoms closely resemble those of ingravescent apoplexy resulting from a hemorrhage into the ventricles, which gives rise to very much the same sort of pressure. Indeed, if ventricular hemorrhage were likely to occur without being preceded by a more localized lesion, there would be nothing to give a clew to the nature of the fluid causing the dilatation of the ventricles. It is possible that some cases of so-called "serous apoplexy" may have been of the kind described here, and considering the small size and inconspicuous location of the lesion, that it may have been overlooked during a hasty autopsy, especially if by accident the ventricles became drained before the examiner had fairly reached them.

The distinction from some cases of meningeal hemorrhage where the clot is equally distributed upon both sides, so as to give rise to no unilateral paralyses, would not be very marked.

In the fourth case much direct pressure was exerted by the tumor on the surrounding cerebral substance, and the symptoms were accordingly complicated by a progressive paralysis of the lower limbs.

CONGENITAL CLUB-FOOT. ITS TREATMENT BY OPEN INCISION AND IMMEDIATE RECTIFICATION.[1]

BY CHARLES N. DIXON JONES, M.D., B.S.,
SURGEON TO THE WOMEN'S HOSPITAL, BROOKLYN; FELLOW OF THE NEW YORK ACADEMY OF MEDICINE, OF BRITISH GYNECOLOGICAL SOCIETY, ETC.

THE results of the ordinary methods of treating club-foot are so disappointing and unsatisfactory that any operative procedure which holds out the probability of removing or overcoming the difficulties encountered by the surgeon should be hailed with delight.

The vast array of mechanical appliances devised and invented, and the great variety of methods recommended by distinguished orthopædic surgeons for the relief of this deformity, are conclusive proof that no easy, certain, and uniformly successful method has as yet been devised. After most carefully planned and skilfully performed tenotomies—after a trial of all the taliverts and boots that have been devised—after a vain attempt to comprehend and grasp the principles of the various mechanical appliances that have been invented—the young surgeon comes at last to the conclusion that anything like a successful method for the treatment of all cases of club-foot is yet to be found.

It is not alone the young surgeon, but as well those of a riper experience who meet with similar disappointments. In a recent address by one of our most distinguished orthopædic surgeons, I find the following expression: "During the past sixteen years, with an unusually large experience in treating this deformity, it has been my good fortune to witness many excellent results, and I am free to confess that I have had my share of failures."

I have no intention of entering at length into a discussion of the various causes of talipes varo-equinus, nor yet of considering all the methods of treatment that from time to time have been practised or recommended, but shall confine myself to a method which has, in my hands, proved of great service in a certain number of obstinate cases, and which is, I think, capable of further extension.

I will, therefore, only make a brief preliminary reference to the factors, pathological and mechanical, which enter into the production of this deformity, so as to be in a better position to estimate the difficulties to be overcome in its successful management. In 1884, Shattock and Parker communicated to the Pathological Society of London an article on the "Etiology and Pathology of Club-foot." Speaking of this report, Mr. Parker says: "Neither of us was prepared to find the nerve-centres, the nerve-trunks, and the muscles of the

[1] Read before the Section on Surgery of the New York Academy of Medicine, December 12, 1887, with presentation of cases.

afflicted limb in a state of absolute histological integrity; neither of us was prepared to find that, after all the soft parts had been entirely removed from the limb, the deformity would persist in just as marked a degree, and in just as intractable a form as previously to the dissection. Yet such was the case."

I shall not stop to consider in detail the etiological factors that have entered into the developmental production of this deformity. In the ordinary process of its evolution, the limb has met with mechanical restraint, whether due to reflex muscular spasm or intra-uterine pressure, and a consequential failure of the foot to pass through its normal rotation, I will not say. It is only necessary for us to remember in the treatment that, independently of the cause, whether spasmodic or mechanical, the limb is maintained in its distorted position by the shortened soft tissues; and while it is true that the bones are deformed, yet they seldom offer a real obstacle to reduction. The muscles, tendons, fasciæ, ligaments, and even the vessels and nerves are altered in length to correspond with the distorted foot and limb. Every tissue contributes its own share in the production of the deformity. If the skin were removed and stuffed, it would still assume the form of the distorted foot. Hence it follows as a corollary of this proposition that every structure entering into the composition of the limb must receive its proportionate share of treatment.

My intention in this paper is not to enter into a detailed description of the various treatments usually applied to talipes, but rather to enforce the surgical deduction drawn from this presentation of pathological facts.

Adams has very truly said: "The scientific treatment of talipes varus can only be accomplished by a judicious combination of the operative, mechanical, and physiological means, while many of the failures are due to the want of this combination of principles."

Numerous operative procedures have been recommended for the purpose of shortening and facilitating the treatment of this deformity. In 1839, Velpeau[1] recommended, first, the division of the tendo-Achillis, and afterward any other tendons which appeared to be tense and prominent, and seemed to interfere with the restoration of the foot. Then, with a powerful instrument for the purpose, he reduced the foot at once to its normal position. Notwithstanding the extensive laceration due to extreme violence, the results of his treatment were far more favorable than one could have anticipated. This method of *brisement forcé* has lately been attended with considerable success in the hands of Bradford, of Boston, and Wolff, of Germany.[2]

Tarsotomy and tarsectomy have both been strongly advocated by various surgeons, and the latter operation has become so popular that no less than fourteen varieties of this operation have been devised and practised. The writings of Vogt, Lorentz, Besser-Hagen, Roser, Phillipson, and Wolff have demonstrated that tarsectomy alone is inefficient in the reduction of the deformity, owing to the resistance on the inner side of the foot.

In 1883, Vogt showed that after the removal of a cuneiform section on the outer border of the foot, notwithstanding the application of great force, he could not separate the firmly pressed bones so as to bring the foot into its normal position, owing to the strong resistance of the soft parts.

In the article above referred to, Mr. Parker says: "In a not inconsiderable number of cases of club-foot, which I have had the opportunity of dissecting during the past four or five years, mostly in stillborn children at term, but including also three cases in children ranging from six to eighteen months of age, the only constant condition which I have found has been inability to overcome the deformity (even after the removal of the muscles) until some of the ankle and tarsal ligaments have been divided." If it is then true that the short, soft tissues on the inner side of the foot offer the only resistance to the rectification of the deformity, and this I think you will all admit, how shall they best be dealt with.

More than forty years ago, an Edinburgh surgeon laid it down as an axiom in the treatment of this affection, that "whatever structures are tense must be divided." But it was not until 1880, almost in the days of pre-antiseptic surgery, that Dr. A. M. Phelps, with one stroke of the scalpel solved the problem. A report of his first case was published in the *Transactions of the Medical Society of the State of New York* for 1881. In 1884, Dr. Phelps read a paper before the International Medical Congress at Copenhagen, entitled "The Treatment of Talipes Varo-equinus by Open Incision and Fixed Extension," which has not been published in this country.

The open operation has not as yet met with the recognition which it deserves. Its reception in Europe has been more favorable than in America. In a recent conversation with Dr. Macewen, of Glasgow, he told the writer that his method of treating obstinate club-foot was either by open incision or tarsectomy. While in Halle, a few months since, Prof. Volkmann showed me several cases which he had treated in this manner. In Schede's clinic at Hamburg the "Phelphsische operation" has become the universal method of treating obstinate cases of club-foot, and Lorentz has recently recommended a modification of this operation by a circular incision around the lower

[1] Broodhurst. [2] Phillipson: Archiv Chir., February, 1887.

border of the internal malleolus, dividing the deltoid ligament.

The treatment of club-foot by open incision and immediate rectification is exercised on the principle of putting the foot in as good a position as it can be made to assume, with the aid of whatever operative procedures are necessary, and fixing it by means of a plaster bandage until the limb has become accustomed to its new position. At the expiration of six weeks or more the plaster is removed, the foot is again fully rectified and fixed in its improved position for another six weeks, and so on until all tendency to relapse is overcome. The manner in which the plaster dressing is applied should receive special attention, it is to be used not as a correcting force but as a fixation splint. This plan of treatment is not new in principle, but it is the manner of carrying it out that is claimed to be especially advantageous.

The method of my preceptor, the late Dr. Joseph C. Hutchison, was "to apply the plaster of Paris and after applying it, twist the foot round in a straight position and hold it there until the plaster sets. After a week it should be taken off and the foot twisted still further, until you finally get it perfectly straight." This plan I have tried and given up; it is tedious, difficult, and it does not answer its intended purpose. The mode of treatment about to be described will meet every indication and is calculated to supersede all other methods.

A description of the treatment of club-foot will be facilitated by a division of the deformity into the following three classes:

1. Those which can be easily reduced by manipulation.

2. Cases where there are contractures of fasciæ and tendons.

3. Cases where all the tissues are greatly shortened.

It is a common observation that certain cases of club-foot in young children, when handled and manipulated, can easily be placed in a normal position; whereas in other cases in which the deformity is less marked, little can be effected without the aid of the knife. It is only in this first class of cases that manipulation and fixation will lead to a permanent result. In the great majority of cases it is but a waste of time to attempt to treat the deformity without division, at least, of the tendo-Achillis and plantar fascia.

It has been my practice, previous to any operative interference whatever, to subject the foot to a thorough process of manipulation and in this way discover the amount of resistance that it is necessary to overcome with the knife, and at the same time eliminate all fibrous bands and adhesions that readily yield to the force of the hand. All who have had much experience in the treatment of talipes must have observed, that even in the infant under chloroform the clubbed foot, when pressed by the hand or other force, into the best position it can be made to assume, immediately on removal of the pressure springs back into its abnormal position. It is, however, possible by a few minutes' manipulation and pressure so to overcome the resiliency of the tissues, that the foot does not so readily spring back into its old position. If the foot be grasped by both hands of the surgeon and gradually but persistently unfolded and twisted into a normal position, at first it gradually yields and becomes improved in position, but soon the shortened structures on the inner side of the foot become tense and refuse to yield, it now becomes a contest between the muscles of the surgeon and the resistance of the deformed tissues. If the force be steadily continued and even increased, not by fits and starts, but continuously and persistently the soft tissues still further yield, the bony surfaces glide on each other, and the foot assumes a position more nearly approaching the normal than would been thought possible. If at any time during this operation there seems to be danger of fracturing the bones, the force used should be intermitted but not entirely let up. If the operation is well performed, at the expiration of ten minutes or so the elasticity of the tissues seems to be exhausted and the foot lies limp and flaccid, without that tendency to spring back which it had previously possessed. More can be accomplished in ten minutes by manipulation in this way than by ten weeks of plaster dressing according to the old method.

It must be remembered, however, that only the simplest cases can be successfully treated without operation, but this preliminary manipulation should form a part of the treatment of club-foot in all its various degrees. Most cases will require at least division of the tendo-Achillis and plantar fascia, and the general rigidity of the foot should be the guide in determining the further extent to which the tendons, fasciæ, and ligaments need division.

Whenever the tense structures on the inner side of the foot prevent its unfolding and rectification, owing to their short condition, they should unhesitatingly be divided by open incision. In this way the time necessary to a cure is shortened, the tendency to relapse is diminished, and the treatment of congenital talipes is placed on a sound anatomical basis. As Dr. Phelps puts it: "More can be done with a scalpel or tenotome in five minutes than can be accomplished in weeks and often months by all the mechanical appliances known to surgery."

In the second and third classes of cases operative procedures are always necessary. As Dr. Lewis Sayre well says, "contractured tissues cannot be stretched."

The distinction between these two classes of cases should be left to the judgment of the surgeon.

It should be our aim to produce rectification of

the deformity with as little operative procedure as possible. In many cases the subcutaneous division of the plantar fascia together with one or more tendons will be all that is necessary, and after their division the distortion can be reduced. But if after subcutaneous division of these structures the foot cannot be replaced, it is better to perform the open operation and divide the tendon of the tibialis posticus, the internal lateral ligament, and all other tissues which offer resistance to the complete redressment of the foot, if necessary, extending the incision to a linear section of the astragalus and other bones of the tarsus.

Operation.—The method of operation is as follows: thorough antiseptic precautions being observed, so as to secure organization of the blood-clot according to the Morris-Schede method. The foot is rendered bloodless by means of an Esmarch bandage. First, the tendo-Achillis is divided subcutaneously, and the foot thoroughly flexed, so as to overcome the equinus. Then an imaginary line is drawn from the process of the internal malleolus to the tuberosity of the scaphoid bone (Fig. 1). Taking the middle portion of

Fig 1.

Line of incision.

this line, an incision is made downward and slightly backward, across the inner side of the foot, following the direction of the transverse wrinkle for a distance of an inch and a half. The nerve and artery may be protected by being drawn to one side of the wound by means of a blunt hook, which is held in the hand of an assistant. The foot is gradually unfolded, and the shortened and contracted structures are divided as they present themselves and offer resistance to replacement, in the following order: skin, connective tissue, tendons of the tibialis posticus, flexor longus digitorum, abductor hallucis, flexor hallucis longus, together with the internal lateral ligament. A tenotome should then be glided beneath the skin, so as to divide the plantar fascia and the muscular structure of the flexor brevis digitorum. These tissues should be cut by a series of nicks rather than by a prolonged incision. The wound is allowed to fill with coagulated blood, and dressed with Lister's protective, sublimate gauze, and a plaster bandage. The first dressing is allowed to remain four weeks, at the end of which time the wound should be healed.

After-treatment.—After the wound is entirely healed, a water-glass shoe is applied, with which the patient is allowed to walk. The glass shoe, if it does not become wet, retains its shape for six to twelve weeks.

Hausmann, of Hamburg, recommends for the after-treatment a shoe which is made as follows: the toes are thoroughly padded with cotton-wool, then the foot is covered with a woollen stocking. A strip of tin one inch in width is applied along the dorsum of the foot, in order to protect the skin when the shoe is cut off. A sole formed of stiff pasteboard is fitted to the foot, and over this another stocking is fitted. A plaster bandage one and a half inches in width is then applied to the foot, so as to form a shoe extending up to the ankle-joint. While still moist, the plaster cast is cut down the dorsum and sprung off. The shoe thus formed is thoroughly dried in an oven, and covered with leather, so as to make a shoe which can be laced up and removed from time to time.

The following cases, which I introduce to the Section, well illustrate what may be accomplished by this operation.

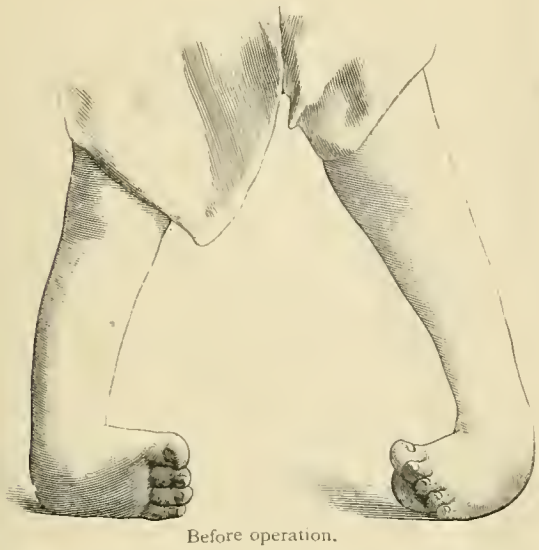
Case I.—Willie C., two and a half years of age, first brought to me on the 21st of March, 1887. The parent stated that when the child was born the feet were markedly deformed and without heels. He was immediately placed under the care of a physician, who put the feet in tin splints, and was thus treated for a period of ten months, but without any material benefit. He was then taken to an orthopædic institution in New York, where the heels were operated upon and a pair of braces applied; with these he was treated, the mother said "tortured," for a period of eighteen months.

When first presented, the feet exhibited a very severe form of talipes varo-equinus, which was further aggravated by inward rotation, or rather hyper-inverted position of the limbs, with slight bowing of the tibiæ. The child walked on the dorsal surface of the feet, where several well-marked bunions had formed. The condition before and after operation is well represented in Figs. 2 and 3.

By firmly grasping the foot and exerting for a few minutes considerable force the position could be somewhat improved, but on relaxing the grasp it immediately sprung back into its distorted position. Phelps's operation was performed on March 26th, assisted by Drs. M. D. Jones and C. A. Canfield.

Division of tendo-Achillis and rectification of equinus. Open incision and division of all the contracted structures. In one foot I also made a linear section of one

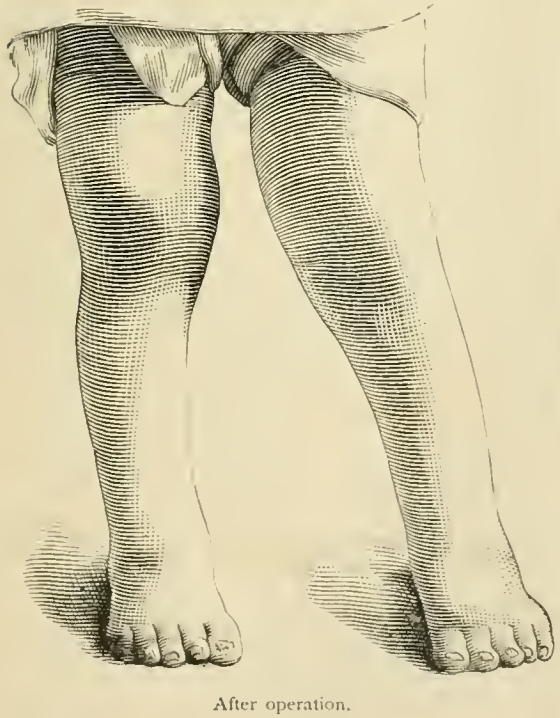
Fig. 2.



Before operation.

of the bones of the tarsus. The foot was placed in the reverse position and dressed with protective bichloride gauze and plaster bandage. No constitutional disturbance whatever followed the operation.

Fig. 3.



After operation.

May 10. Dressings removed, foot in good position, wounds not entirely healed.

17th. Feet redressed, wounds entirely healed. Up to the present time the water-glass splint has been applied three times, and for several weeks during the summer they were without any support whatever. At present the feet show good size, shape, and function. The inversion of the tibiæ still exists.

Case II. (Case presented.)—Tommy S., aged five years, was brought to the hospital May 5, 1887. He presented a well-marked example of double equino-varus, which was congenital. According to the mother's statement, when nine months old he was operated upon by a surgeon who cut both tendo-Achillis. At first he was treated with plaster splints, but during most of the time has worn braces, which have been changed from time to time as the feet increased in size, but with little improvement. Thus during a period of four years he has undergone constant treatment at the hands of a distinguished orthopædic surgeon in one of the Brooklyn dispensaries.

State on examination.—The feet were rigid, inverted, and the inner side very much shortened. The use of the braces had produced large bunions and excoriations on several of the prominent parts of the limbs.

Operation May 6, 1887. Under an anæsthetic and assisted by Drs. M. D. Jones and A. M. Phelps—the latter had recently removed to New York—I divided subcutaneously the tendo-Achillis and by open incision all the tense structures on the inner side of both feet. After dressing, the feet were put into Phelps's machine and the plaster moulded into position.

June 2. Dressed, wounds healed and feet in good position. Patient has continued to wear the water-glass shoe with the exception of a few weeks while at the seaside during the summer.

October 20. Fixed shoe applied; good size, shape and function of feet.

I am much indebted to Dr. Phelps for treatment of this case during an absence in Europe.

When we consider that during a period of eight months these cases have been seen by the surgeon, at most only five or six times, I think we may very properly ask ourselves, is there any other operative procedure that will produce as good a result as is shown by these cases, with the same expenditure of time and trouble on the part of the surgeon? I cannot more appropriately close this paper than by quoting the words of Professor Gibney, used in a recent address: "I would have the conclusion drawn that the successful management of this deformity depends upon the close study of individual cases, on a clear anatomical diagnosis, and on a faithful adherence to whatever method is adopted, recognizing and fully appreciating the difficulty in securing at all times the hearty coöperation of the parents. I would have a conclusion drawn that that method should be adopted which depends the least upon this coöperation for success."

HOSPITAL NOTES.

JEFFERSON MEDICAL COLLEGE HOSPITAL, PHILADELPHIA.

A Case of Hysterical Trismus.

Reported by Orville Horwitz, B.S., M.D.,
chief of the outdoor surgical department, and demonstrator of anatomy in jefferson medical college.

The patient, who was a thin, nervous woman, aged twenty-three years, by occupation seamstress, when brought to the hospital was suffering from trismus, presumed by her attending physician to be due to inflammation of the temporo-maxillary articulation with the resulting formation of artificial bands, a sequence of tonsillitis.

Five months previous to presenting herself she had an attack of acute tonsillitis, which ran the usual course, but was followed by rigidity of the temporo-maxillary joint; the upper and lower jaw being separable to the extent of about one-quarter of an inch. This condition continued until she applied for treatment. She had subsisted entirely upon liquid food, and consequently was weak and emaciated. Owing to her presumed inability to open the mouth, the tonsils and fauces could not be examined.

After careful examination of the case, the writer arrived at the conclusion that it was one of hysteria. The patient was told that if she would allow herself to be placed under the influence of an anæsthetic a slight operation would be performed whereby she would be completely cured; to this she cheerfully consented. As soon as she lost consciousness the mouth opened, and, on examination, the throat was found to be in a normal condition. A mouth-gag was inserted and allowed to remain until the effects of the ether had worn off, that the patient might see that the jaws had been completely separated. When consciousness was fully restored, she opened and shut her mouth without difficulty.

A tonic was prescribed, and she left the hospital with expressions of gratitude for the relief that had been afforded her.

MEDICAL PROGRESS.

The Treatment of Retained Placenta at the Rotunda Hospital, Dublin.—In the *Practitioner* for December, 1887, Dr. Lane describes the method pursued at the Rotunda Maternity as follows: When the placenta is adherent I believe the proper treatment is to pass the hand or fingers into the uterus and detach it, although I have been informed that some Continental obstetricians allow the placenta in such cases to remain for even a month after delivery (unless there is hemorrhage or symptoms of septicæmia), especially in the cases where the patients have not come to their full time. I consider, however, that if the operator's hands be not perfectly aseptic, this is the most dangerous of all operations met with in midwifery practice, except the Cæsarean section. It has been recommended by some authorities to keep the fingers inside the membranes during the operation, but there are many cases met with where, owing to the friable nature of the placenta, necessitating the removal of small pieces at a time, this is impossible. Should there be any septic infection about the hand, and especially about the nails, the usual seat of such poison, I failed to see how such a patient can escape becoming infected; for it is analogous to vaccination, except that virulent poison is substituted for healthy lymph, and with unfortunately greater likelihood of its taking effect, owing probably to the prolonged contact. The uterus, except where it has been already douched out with the hope of getting the placenta away, as I have already mentioned, is always douched with antiseptic solution prior to introducing the hand. Although the left hand is recommended by many as being smaller and corresponding more with the pelvic curve, the right hand is the one generally used, for, the patient being in the obstetrical position usual in this country, the fundus of the uterus can be better and more easily supported by the left hand (the operator standing at the patient's back). Nor can an assistant, no matter how experienced he may be, support the uterus so satisfactorily as the operator himself, who knows the exact part of the uterus requiring pressure so as to bring that particular part of the uterine wall nearer to the introduced hand, and who is able to remove it to some other part the moment required.

An anæsthetic, usually chloroform, is nearly always administered, in order that, if necessary, the hand may be passed in a second time where doubt exists whether all the placental tissue has been detached; for if the patient be perfectly conscious of what is being done, the operator must be very resolute to be able to withstand her solicitation not to pass the hand a second time, and I consider that, once the hand is introduced, the operation should be persevered in to entire completion. When satisfied on this point, the uterus should be again douched out with antiseptic solution.

The Treatment of Headache Caused by Chronic Pharyngitis.—Vergely recommends the following application to the throat, by a camel's hair pencil, followed by a gargle of warm, salt water:

Glycerin.,	
Tinct. iodin.,	
Aquæ destill.	āā ♏ 75.
Potass. iodid.,	
Cocain. hydrochlor.	āā gr. 7½.

In general treatment quinine, in 8 grain doses, with 30 grains of potassium bromide, was given. Aconitine or morphia may also be employed.

When anæmia is present the following pill may be used to advantage:

Ferri oxalat.	gr. 1½.
Ext. rhei	gr. ½.
Ext. nucis vom.	gr. $\frac{1}{20}$.

—*Revue Générale de Clinique et de Thérapeutique*, December 22, 1887.

Solvin.—Kobert, of Dorpat, in the *Therapeutische Monatshefte* for December, 1887, describes under the name *solvin* a substance produced by the action of sulphuric acid upon glycerine-ether, as in the action of the acid upon oil of almonds and castor oil. This substance has been recently introduced as a solvent for iodoform, naphthalin, salicylic acid, salol, and a great variety of substances. It is a clear, oily liquid, capable, in very

small quantities, of forming emulsions. Kobert's experiments upon animals have shown that solvin possesses poisonous properties, and that it should be introduced into the organism with caution.

The Treatment of the Throat in Diphtheria.—DR. BARUCH, of New York, in the *Medical Record* of December 24, 1887, describes his mode of treatment as follows:

Disinfection of the throat is best accomplished by the frequent internal administration of tonic, astringent, and antiparasitic remedies; not by the brush, probang, or atomizer. Neither water nor food should be permitted for ten minutes after the medicine has been swallowed, thus allowing it to bathe the diseased surfaces. When the patient is tractable and willing to aid the attendant, I advise the hourly application of a fifteen per cent. solution of trypsin. In one case a ten per cent. papayotin solution proved equal to trypsin, but much more expensive. In nasal diphtheria the trypsin solution is invariably prescribed, to be applied hourly with the medicine-dropper or soft brush, because this can be accomplished without damaging the mucous membrane even in an intractable child. It softens and pulpifies the false membrane, and facilitates its removal by injections of salt water, or 1 : 10,000 bichloride, which in this dangerous form I order applied at frequent intervals. It will appear, therefore, that while I abstain from local treatment in most cases of faucial diphtheria, I apply it vigorously, but gently, by the brush and soft rubber-tipped syringe in all cases of nasal diphtheria. When the air-passages are involved I also resort to local treatment by inhalation of the vapor from boiling lime-water impregnated with oil of turpentine—one ounce of the latter to one quart of the former, used continuously. Properly applied, these inhalations have aided me in saving several of my patients from tracheotomy.

Purgation after Abdominal Section.—MALCOLM, Assistant Surgeon to the Samaritan Free Hospital for Women, publishes in the *Lancet* of December 24, 1887, the following notes of a case of abdominal section, for ovarian tumor:

Sir Spencer Wells went abroad on the third day after the operation, leaving me in charge of the case. On the evening of the third day, and all through the fourth day, there was a tendency to sickness and abdominal distention, but flatus passed freely from the rectum. On the fifth day that portion of the bowel was found to contain feces, and a small enema produced a copious evacuation, after which the feeling of sickness and the distention passed off. The action of the bowels was followed by considerable pain in the right groin about the position of the pedicle, and the temperature rose in a few hours to 100° in the axilla, but again gradually fell to 98° on the seventh day after operation. The bowels moved seven times between the fifth and tenth days, and much flatus also escaped. During this time, however, the pain in the right groin increased, until the patient could not bear the slightest pressure over this part. The rest of the abdomen became slightly distended, but was free from tenderness. The administration of one-sixtieth of a grain of atropia and one-twelfth of a grain of muriate of morphia, repeated every four hours, eased the pain; but the appetite became very bad, and the patient felt constantly sick after the eighth day. She also lost strength, and her pulse, which had been down to 84 and of good character, gradually rose to 100, and became very feeble. On the tenth day her temperature, which had not been above 98.6° for two days, also began to rise a little, and reached 99.6° in the axilla at 9.30 A.M.; she had been very restless all night, could not take any food, and felt very sick, while the abdomen had become more distended. This grouping of symptoms after abdominal section I have learned to associate with obstruction in the bowels, which may lead to a rapidly fatal termination of the case. In the belief, therefore, that my patient was in extreme danger from this cause, and that the best method of treatment of this condition at this stage is by the administration of a purgative, I gave her a pill containing one-third of a grain of calomel and as much jalap, one grain of compound extract of colocynth, one grain of extract of aloes, one-twentieth of a grain of jalapine, and a little ginger. The patient had frequently used similar pills, prescribed by her own medical attendant, Dr. Morley, of Blackburn, and they had moved the bowels gently during health. On this occasion the pill produced two small loose motions, and a dose of Hunyadi water, given next morning, was followed by other loose motions. The last of these was at 5 P.M. on the eleventh day after operation. Twelve hours after the pill was given the temperature had risen to 100.6° in the axilla, perspiration was extremely profuse, and the patient had become alarmingly weak, but she was then able to take food without feeling sick. After the bowels were quiet twenty minims of tincture of opium were given by the rectum, and the patient had a good night's rest. She was much stronger next morning, and this improvement continued. The pain in the right groin, however, became more severe, and the tenderness radiated over the abdomen to some distance from this part. The temperature continued feverish but irregular till the thirteenth day, when it fell to normal and remained so. On this day also the pain shifted upward and toward the right loin, and next morning there was only slight tenderness on pressure in the groin and none in the loin. Now, however, the patient at once complained of pain when I applied pressure over the colon in the region of the gall-bladder. The seat of tenderness afterward shifted from time to time along the course of the colon, and finally was found low down in the left groin on the fifteenth day after the operation. The bowels had then been quiet for four days, and I warned the patient that she would soon have an action of the bowels with considerable pain. That afternoon several large, very hard fecal masses passed into the rectum, whence they were removed with some difficulty by the nurse, after which recovery was uninterrupted.

A Laxative Gastric Tonic.—BARDET has used to advantage:

Ext. fluid. cascara sagrad. . . .	ʒ 5.
Tinct. nucis vom.	♏ 30.
Aquæ destil.	ʒ 28¾.
Syrup. simpl.	ʒ 3¾.—M.

Sig. Dose, a teaspoonful.—*Journal de Médecine*, December 18, 1887.

Movable Kidney.—DR. GRANT, of Melbourne, concludes an extended article in the *Australian Medical*

Journal of November 15, 1887, upon this subject, as follows:

1. That mobility of the kidney, even though slight, is no mere anatomical curiosity, but a condition of real clinical importance, producing serious disturbances of function in various organs.

2. That it produces its effects chiefly by reflex irritation of these organs through the sympathetic centres, and but little by its mechanical action.

3. That the irritation may influence the sensory, motor, or secretory functions of the organs affected.

4. That variations in the character and intensity of the symptoms may be accounted for by variations in the intensity of the irritation, a minor intensity stimulating, and a major intensity paralyzing, certain reflex centres.

5. That the so-called strangulation of the kidney is probably due, not to a mechanical or inflammatory obstruction, but to sudden and extreme intensification of the irritation.

6. That in all cases of obscure abdominal pain, a systematic search for a movable kidney ought to be made.

7. That a certain peculiar localization of intestinal disturbance forms presumptive evidence of movable kidney.

8. That the diagnosis rests on palpation, the results of inspection and percussion being of no value, and the rule usually given as to the latter being probably contrary to the fact.

9. That, as the condition does not threaten life, and is not inconsistent even with great longevity, no operation involving danger to life is justifiable.

10. That mechanical appliances may palliate, but cannot remove the symptoms.

11. That the rational treatment consists in endeavoring to restore the natural pad of fat, and in diminishing the reflex irritability, and that for the latter purpose codeia is peculiarly adapted, on account of its special power of lessening the irritability of the afferent fibres in the nerves of the abdominal viscera.

The Bacteria of Whooping-cough.—Aphanasieff, a Russian observer, has found in the sputa of those having whooping-cough short, small bacteria, which, when inoculated into the respiratory passages of puppies and rabbits, produced an affection almost identical with whooping-cough. They always settled themselves in the trachea and bronchi of animals, and were found in the lungs of children who died of whooping-cough. The name *bacillus tussis convulsivæ* was proposed.—*Le Bulletin Médicale*, November 20, 1887.

A Case of Endolaryngeal Epithelioma, Destroyed by the Galvano-cautery with Success, Twenty Years ago.—Schnitzler is quoted by the *British Medical Journal* of December 17, 1887, in an article on the diagnosis and treatment of endolaryngeal neoplasms, in which he relates the case of a woman in whom he had destroyed an epithelioma of the larynx by the galvano-caustic method twenty years ago, and who was still living. The diagnosis of epithelioma had at the time been fully confirmed microscopically by very competent and trustworthy pathologists. He was nevertheless afraid that, on hearing the case, some might be disposed to make the usual comment referred to in the following remark of Ducarques: "Le cancer est incurable parcequ'on ne le guérit pas ordinairement; on ne peut le guérir puisqu'il est incurable; donc quand on le guérit, c'est qu'il n'existait pas." The following are the details of the case: E. L., an actress of Prague, twenty years of age, was, in January, 1867, admitted into the clinic of the late Prof. Türck, of Vienna, for persistent hoarseness. Prof. Türck stated that vegetations of the vocal cords were the cause of the voice affection. Repeated operations performed by him with the knife (in February and June, 1867) were only temporarily successful. When the patient came, some months later, into the clinic of the late Prof. Oppolzer, she was almost absolutely aphonic, and also complained of considerable difficulty of breathing. Prof. Schnitzler, who was then assistant to Prof. Oppolzer, found that the vocal cords were much swollen, and detected the presence of red vegetations of a granular appearance at their inner side. The vegetations almost filled up the rima glottidis. In spite of the youth of the patient, Prof. Schnitzler diagnosticated epithelioma, and immediately removed the vegetations, which already threatened to suffocate the patient. The first piece of a large size (of the size of a cherry-stone) which was removed by the galvano-caustic loop, was microscopically examined by Drs., now Professors, Biesiadecki and Scheuthauer, then assistants of Prof. Rokitansky. Both these experts pronounced the growth to be epithelioma. Prof. Schnitzler afterward heard that Prof. Türck had also at once made the diagnosis of epithelioma, and that his diagnosis had been confirmed by the microscopical examination of Prof. Wedl. Prof. Schnitzler had repeatedly destroyed the disease by galvano-cautery, and was happy to be able to show the patient at the meeting of the Imperial Royal Society of Physicians of Vienna on October 16, 1868, as being cured, that is to say, as far as we are entitled to speak of the cure of epithelioma. The patient was still hoarse, but her voice could already be distinctly heard, and the dyspnœa had completely disappeared. No trace of the growth could be discovered (see Report of the Society of Physicians of October, 1868). The patient remained under the observation of Prof. Schnitzler for some years longer, and he thought it possible that she might have lived for ten years after the operation. Before, however, he published the case, he wished to obtain exact particulars as to the patient's fate, and, therefore, applied to the physician who had in the first instance sent the patient to him. To his great surprise he learned that she was still alive, and that the physician had seen her only recently at Prague, twenty years after the laryngeal epithelioma had been destroyed. Prof. Schnitzler went on to ask if it was possible that such excellent microscopists as Biesiadecki and Scheuthauer could have made a mistake. He could not believe this, as their diagnosis was quite positive. After all, why should not recovery take place after the galvano-caustic destruction of an epithelioma, as well as after an extirpation with the knife? The possibility of curing some kinds of carcinoma was, as is well known, admitted by Rokitansky.

Adulterations of Antipyrin.—The *British Medical Journal* of Dec. 17, 1887, remarks that recent investigations have shown that antipyrin is frequently adulterated with benzine and phenylhydrazine. Antipyrin does not change litmus paper; it is easily soluble in water, alcohol, and

benzine; it is also soluble in chloroform and glycerine, but not so quickly. Treated with picric acid, chloride of gold or platinum, antipyrin gives a yellow precipitate; with perchloride of iron a blood-red precipitate is obtained; nitrous acid produces a green precipitate, and permanganate a blood-red precipitate. The presence of phenylhydrazine in antipyrin is shown by the reduction of Fehling's solution. The presence of benzine is detected by Berthelot's process. Antipyrin is mixed with nitric acid; ether is added; the liquid is then filtered and distilled; chloride of lime is added, and if the antipyrin contains benzine, the mixture assumes a violet hue.

Iodide of Sodium in Phthisis.—POTAIN has found the following a convenient formula:

Aquæ destillat.	ʒ 25.
Sodii chlorid.	ʒ 2½.
Sodii bromid.	grs. 75.
Sodii iodid.	grs. 38.

A dessertspoonful in the morning, in a glass of milk. This combination contains the salts found in cod-liver oil, and is of value in the treatment of the scrofulous and those in whom tubercular disease pursues a slow course. —*Revue de Clinique et de Thérapeutique*, December 8, 1887.

Aceto-tartrate of Aluminium, a New Antiseptic.—ATHENSTALDT prepares this substance by mixing a solution of 5 to 100 of acetate of aluminium and 2 to 100 of tartaric acid; the double salt formed is obtained by evaporation. The aceto-tartrate of aluminium is a brilliant, colorless mass resembling gum arabic in appearance. It has an odor of acetic acid, and dissolves readily in water. Its taste is acid, slightly astringent, not disagreeable. It dissolves in equal parts of water; the solution remains clear when heated. It is precipitated by alcohol. Its chemical composition is that of a double salt. When exposed to the air it becomes less soluble, through the loss of a portion of its acetic radicle. It is an innocuous antiseptic.—*Journal de Médecine*, December 18, 1887.

The Treatment of Epistaxis by Hot Water.—The Paris Correspondent of the *British Medical Journal* of December 17, 1887, writes that DR. ALVIN, consulting physician at Mont-Doré, recently treated a case of serious epistaxis by irrigation. The bleeding came from the right nostril. The blood trickled through the plugs, and forced its way through the puncta lachrymalia. The nose was swollen, owing to the collection of blood in the nasal fossæ. The dressing was removed. The blood flowed abundantly. Irrigation was performed with water at 65° to 70° C. (149° to 158° F.) by means of an English irrigator. The water returned through both nostrils and through the throat. In two or three minutes the bleeding was checked. The operation was not painful, notwithstanding the high temperature of the water; it was repeated twice during the evening. M. Alvin concludes that irrigation with hot water is an efficient, safe, and painless method of treating epistaxis. The patient should be watched for ten hours after the operation, in case it may be necessary to repeat it.

Two Successful Porro Operations.—PETERS, assistant to Gustave Braun, of Vienna, reports two successful Porro operations for osteomalacia. One child was stillborn; the other died fourteen days after birth from intestinal catarrh. — *Wiener medicinische Presse*, December 18, 1887.

Caffeine Intoxication.—GUILLIOT, in the *Revue Générale de Clinique et de Thérapeutique* of December 15, 1887, describes the "coffee sot" as follows:

The skin is pallid, yellowish, and slightly cadaveric. The face is that of a person prematurely aged; when coffee is used to great excess it is slightly swollen. The body is emaciated, muscular atrophy being present in marked degree. The eyes are brilliant, the pupils somewhat dilated and lacking in expression; the tongue, the lips, and the facial muscles about the mouth are tremulous, and present a characteristic appearance. In 23 cases the following disorders were found, which could be ascribed to coffee. Anorexia in 18 cases; disordered sleep in 16 cases; tremors of the tongue and lips in 16 cases; leucorrhœa in 12 cases; gastralgia in 11 cases; dyspepsia in 10 cases; various neuralgias in 10 cases; cephalalgia in 8 cases; vertigo and convulsive attacks in 4 cases; persistent constipation in 4 cases; constipation alternating with diarrhœa in 3 cases. In treating these cases it is best to stop the use of coffee at once, if the patient will consent; troublesome insomnia may follow, but this must be met by sedatives. The general treatment is tonic and hygienic.

Sodium Fluosilicate, a New Antiseptic.—DR. HAYWARD describes this newly introduced substance as follows, in the *British Medical Journal* of December 24, 1887: Sodium fluosilicate, the new antiseptic which has recently been coming into use, promises to prove an equally effective and much safer substitute for corrosive sublimate in midwifery practice. It is but slightly soluble in water, only to the extent of about two-thirds per cent. at 60° F.—that is, a pint of water will dissolve about fifty grains. It should be used in saturated solution. A few powders of fifty grains each will form but a trifling addition to the weight of the midwifery bag.

Antipyrin in Solution.—The following has been found a convenient formula for a solution of antipyrin:

Antipyrin	gr. 75.
Aquæ destill.	ʒ 20.
Rum	ʒ 5.
Syrup. limon.	ʒ 7½.

Each teaspoonful contains between 2 and 3 grains.—*Journal de Médecine*, December 18, 1887.

The Treatment of Lacerated Perineum at the Dublin Maternity.—DR. LANE describes, in the *Practitioner* for December, 1887, the treatment employed in the Rotunda Hospital as follows:

When the perineum is lacerated over three-fourths of an inch in extent, the practice is, having douched out the vagina with antiseptic solution, to suture immediately either with silk or catgut (using in the latter the continuous suture).

The results have been very satisfactory, chiefly owing, he thinks, to the stitches being inserted deeply so as to bring the whole of the torn surface into apposition. For if this be not done the lochia would probably collect

between the edges of the wound, causing them to become unhealthy, especially should the discharge be fetid, and this unhealthy condition when once produced is very likely to go deeper, until possibly it might invade the whole depth of the perineum, causing the stitches to slough out, and the wound to gape widely open. Dr. Lane considers that a patient whose perineum has been lacerated in the first confinement (especially if the child were large), and that it has afterward united properly, is much less likely subsequently to suffer from relapse than if the perineum remained intact, for in the latter case it would show that the parts were very relaxed.

Strophanthus.—Haas, of Prague, concludes, from his clinical study of strophanthus, that the apex beat of the heart is much less distinct under the influence of strophanthus than under the influence of digitalis: the latter drug produces a sharply defined pulsation, while strophanthus does not so clearly mark the boundaries of the cardiac area, which becomes diffuse.

In cases where an exaggerated second pulmonary sound is present, the accentuated quality disappears under the use of strophanthus. The frequency of the pulse is, in the cases described, regularly lessened.

In three cases of stenosis of the cardiac apertures of high degree, the patients became cyanotic after taking strophanthus, complained of great dyspnœa, and went into collapse.

Haas found that patients suffering from fever bore much larger doses than those who had no fever; fifty drops of the tincture and more were given to fever patients without ill effect, while thirty drops, in twenty-four hours, was the usual dosage for patients not suffering from fever.—*Therapeutische Monatshefte*, Dec. 1887.

Trephining for Meningeal Hemorrhage.—A female patient, aged twenty-six, was admitted under the care of Mr. Croft, in St. Thomas's Hospital, about midnight on Dec. 11th, in a semi-comatose condition. She was supposed to have been knocked down and kicked by a horse. There was a scalp wound, not leading down to bone, behind and below the left parietal eminence. There was no evidence of fracture. During the night she passed into a state of absolute coma, and in the morning had complete paralysis of the right arm and leg, but not of the face. Mr. Croft trephined in the situation of the wound, removing about two ounces and a half of somewhat granular clot, which was spread out for some distance between the dura mater and the bone. The hemorrhage was from some vessels in the dura mater (probably posterior branches of the middle meningeal), and could only be arrested by pressure. About six hours later the power of movement returned in the right side, and her condition gradually improved. She spoke for the first time after the injury on the 13th. Although not yet recovered, she is still restless at times, and impatient of control; there is no paralysis, the wound is quite aseptic and healing, and the improvement continuous. A severe contusion of the groin was, however, followed by sloughing and cellulitis, for which incisions were required.—*Lancet*, December 24, 1887.

Chlorine Water in Ulcers of the Pharynx.—Dr. Wise, in the *Maryland Medical Journal* of December 31, 1887, describes the case of a child whose tonsils, uvula, and pharyngeal space were covered with yellowish-white ulcers. The mother was apparently suffering the most; her tonsils were literally covered with ulcers, scarcely any normal gland tissue visible, while the pharynx and uvula were dotted with ulcers of various sizes from the palate to the surface opposite the trachea—very offensive breath and swollen cervical glands, headache, and severe pain upon deglutition.

After a gargle of permanganate of potash, insufflated calomel and chlorate of potash 1–3, I prescribed the following solution:

R—Potassii chloratis . . .	℥ss.
Acidi hydroch.	℥j.—M.
When gas formed ad.	
Aquæ	℥iv.
Quiniæ sulph.	℥ss.

Sig.—A tablespoonful every four hours in a half glass of cold water, and dose proportionate to ages of children. Also, Tr. ferri chloridi, gtts. xx, every four hours.

In forty-eight hours the throat was perfectly clear—mucous membrane normal in color, with a healthy granulating surface at base of ulcers, and almost healed.

With the change of the solution, by adding the iron thereto, I have found its action in diphtheria equally satisfactory.

Rodent Ulcer of the Rectum.—Dr. Norton, in the *Medical Press and Circular* of December 14, 1887, describes his treatment of this affection as follows:

Among poor people when the ulcer has existed some few years, it is probable that the patient has already been treated at more than one hospital, and, as in doubtful cases of cancer, syphilitic treatment has had a fair trial, but without any success. It is clear that nothing but a destructive treatment can be of service; one may, therefore, employ a solution of pernitrate of mercury or of chromic acid, or the ulcer may be scraped, or the question arises whether it is advisable to remove the whole surface by a very shallow excision; in order to overcome the stricture the usual methods of treatment are employed, namely, the bougie, sudden dilatation, and incision. Dr. Norton has used the mercurial solution with advantage in these cases, though he does not claim to have cured the disease, and he has also used it with markedly good results in cases of epithelioma of the palate and pharynx, with unmistakable relief and retardation of the growth. He thinks this method of treatment in epithelioma, where it is difficult or dangerous to excise, has not been sufficiently practised by surgeons, and he sees no reason indeed why, with cautious and continuous application of selected escharotics, the growth should not be destroyed almost as completely as by removal with the knife. He has scraped the ulcerated surface, but find it difficult by this means to remove all that he desires. The cases in which he performed colotomy were treated by gradual dilatation for greatly constricted passage, and in all these the operation was resorted to because the passage of the bougie gave rise to an irregular rise of temperature, characteristic of septicæmia. Immediately after the operation the temperature subsided. Of these three cases one was soon lost sight of, the other two are still alive, one after a space of about five years, and the other two years. One continued her employment as a servant of all work for some years, the other, who is a married woman, has been incapacitated from work the whole time.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JANUARY 21, 1888.

EXTRAPERITONEAL EXPLORATIVE SECTION.

EXPLORATIVE incision of the abdominal walls has become one of the most common of all operations; in fact, almost all abdominal operations may be called exploratory, as it is impossible to foretell exactly what will be found. The simple exploration of the abdominal cavity for diagnostic purposes is attended with but little danger, and yet it must be admitted that the opening of the peritoneal cavity for this purpose ought to be avoided when possible.

At the Second Congress of Russian Physicians, PROF. W. SNEGUIREFF recommended exploration of the abdomen by means of incisions which did not go through the peritoneum, and subsequently BARDENHEUER published a communication upon the same subject in the *Deutsche med. Wochenschrift*, No. 13, 1887; and, recently, DR. A. VON GUBAROFF has presented a short paper upon extraperitoneal exploration in the linea alba, in the *Centralblatt f. Chirurg.*, No. 47, 1887.

Bardenheuer recommends the extraperitoneal exploration because it is less dangerous on the one hand; and, on the other, a large proportion of abdominal tumors are situated either extraperitoneally, or at least can be grasped much better from behind. It was found that the peritoneum could be easily separated for a large space without becoming gangrenous, and that by so doing, it became possible to examine and even remove tumors. This principle is not new, only its application has been somewhat extended, for all surgeons are familiar with separation of the peritoneum in the ligation of the iliac arteries, the removal of the kidney, the sectio alta, etc.

Bardenheuer describes three forms of extraperitoneal incision, the renal, the hypogastric, and the thoracic. The renal incision was found of value, not only for the removal of retroperitoneal tumors, but for palpation of the liver, head of the pancreas, the duodenum, colon, cæcum, and spleen. The hypogastric incision is made in a transverse direction above the symphysis, and is useful for the removal of calculi or tumors from the bladder. He has removed myomatous and carcinomatous uteri several times, and an extrauterine fœtation, almost extraperitoneally; and thinks the Cæsarean section may be performed in the same manner. The thoracic incision follows the bony boundaries of the thorax, and allows the detachment of the peritoneum from the tendinous centre of the diaphragm, without tearing.

Sneguireff and Bardenheuer each recommend lateral incisions for diagnostic purposes, but von Gubaroff pleads for section in the linea alba. He says the peritoneum can be readily detached to the extent of an inch on each side of the linea alba, and its elasticity permits an examination of almost the whole peritoneal cavity. He recommends it as a preliminary act in all cases of diagnostic laparotomy, because it is devoid of danger; and if the serous membrane is torn, the usual exploratory operation can be immediately performed. We present these views because the method seems to have a certain range of usefulness, but most surgeons will prefer to have the advantage of inspection as well as of palpation in those cases in which the diagnosis is obscure.

THE TREATMENT OF PULMONARY TUBERCULOSIS BY CREASOTE.

IN the *Medicinische-Chirurgische Rundschau* for June, 1887, is a communication by SOMMERBRODT, of Breslau, on the use of creasote for the treating of phthisis. In this paper are reports of no less than five thousand cases treated in this way, during a period of nine years, all the patients being still able to be about. Using the formulæ devised by Bouchard and Gimbert he obtained no less than twenty-seven recoveries out of every hundred cases.

The formulæ were chiefly as follows: 15.3 parts of creasote to a quart of alcohol or Malaga wine, and 2 parts of creasote to 150 of cod-liver oil. From 3 to 5 minims of these two mixtures were taken daily, and in some instances he also used

creasote 3.5 parts, alcohol and water each 125 parts. Of the last as much as a teaspoonful was ordered twice daily in a glass of water.

Another method consisted in using gelatine capsules, after the manner of Reuss, each of which contained three-quarters of a minim of creasote and 3 minims of balsam of tolu. For the first twenty-four hours the patient took one, after that two, and for the succeeding eight days three in each twenty-four hours. When two weeks had passed the dose was increased to four capsules, next to five capsules, and in the fourth week as many as six capsules were given daily. Only in rare cases was the remedy badly tolerated.

When given to young persons the results were better than when administered to older ones, and climatic changes were also productive of very good results when combined with the use of the drug. Naturally it was noted that incipient cases were more improved than those cases which had already run a long course. In those instances where scrofulous glandular affections seemed largely present, this treatment was particularly successful, the irritable cough was relieved, narcotics were no longer required, and both bronchial and cutaneous secretion diminished. The action of creasote is, however, most slow, three months or a year being required before any great change can be expected.

The *Berliner klinische Wochenschrift* of July 6, 1887, also contains a discussion of the paper of FRÄNTZEL on the same subject by such men as GÜTTMANN, THORNER, LUBLINSKI, and ROSENHEIM, in which evidence was brought forward that this method of treatment is not so universally valuable as might be hoped.

SOMMERBRODT, in the *Berlin. klin. Wochen.* of November 28, 1887, defends his first paper, as far as defence is necessary, and evidently believes that very minute doses of creasote, such as have been used by some clinicians, are valueless.

The treatment of phthisis by creasote seems, from the results so far reached, to be at least worthy of further trial, and may be tried with advantage, perhaps, in those cases where other remedies seem valueless, or for some reason are contraindicated.

INACCURACIES IN THE HISTORY OF SPLENECTOMY.

IF statistical records of surgical cases are to have any value, they should, at least, represent the facts and exclude the fabrications, or erroneous statements of the past. No tabular record can be received with entire confidence unless the searches are known to have been made *de novo*, and from the original sources of information. And we must confess to being very sceptical about the carefulness of much of our statistical work, having so often detected inaccuracies when least expecting them. Fortunately for those who prefer to trust to their own labors, rather than to those of others, the large library of the College of Physicians of Philadelphia, and the still larger one in the Surgeon-General's Office, in Washington, furnish the means of consulting nearly all of the original publications that may be required; the few that must remain being attainable through correspondents in the older collections of European libraries.

Our literature shows how much more easy it is to perpetuate an error than to eradicate it after it has been copied and recopied, time and again. In illustration of this, we will take up the subject of splenectomy, confining our remarks to the extirpative operation for disease or displacement of the spleen. This is generally supposed to be a very ancient operation, and would be, if we could credit the original sources of information, but here is where we fail to be at all satisfied, and after weighing all the claims, come at last to the opinion, that a diseased spleen was first removed at Rostock, in Germany, by DR. QUITTENBAUM, only fifty-one years ago, *i. e.*, October 5, 1836.

If we could believe the oft-repeated statement of splenectomists, the initial operation was performed at Palermo, in April, 1549, by Adriano Zaccarello, of Palo, a town in the kingdom of Naples. But the best authorities in Italy make no claim to the case, and through them we learn the total unreliability of its historian, Leonardo Fioravanti, who in one of his eight books, *Tesoro della Vita Umana*, Venice, 1570, page 25, makes the statement that the said Zaccarello removed the spleen with a razor, and that the lady recovered. Perhaps Italy never produced a more notorious travelling charlatan and quack medical writer than Fioravanti, of Bologna, who ranged from Venice over the whole Italian Peninsula in his round of practice; and Zaccarello was of the same type, cutting for stone, operating for cataract, etc. Is it at all likely that such a man could properly ligate and remove a spleen of two pounds in weight, so as to secure success 338 years ago? Besides, Fioravanti's story did not appear until twenty-one years after the operation was said to have been performed, and if

he was worthy of credence we should have to add a second case, his own special work, done in Naples in 1551, as he states in another book; but this operation appears to have been overlooked.

The second historical case in order has been credited to "Ferrerius," in 1711, with a like fortunate result. Ferreri's operation was certainly not a splenectomy surgically considered, although the patient lost her spleen. The subject was a plethoric woman, thirty years old, who had an abscess of the spleen, with a fistula near the umbilicus. Ferreri opened the abscess, the splenic tissue broke down, and finally the capsule came away. The woman bore a child afterward, and in 1716 died. At the autopsy, no spleen being found, a report became current that it had been extirpated. Cases similar to this have since occurred, and one of them quite recently in this country.

A third success has in some tables been credited to Dr. Fantoni, of Milan, who certainly was not a splenectomist, according to the best Italian authorities. Our experience teaches us that Italian surgical historians make very decided claims to priority where they believe them to be well founded; and as they now reject all the three cases enumerated, the rest of the world may be content to drop them.

A fourth case has crept into literature through careless translating, and Dr. Volney Dorsey, of Piqua, Ohio, figures in table after table as D'Orsay, a successful splenectomist. Dr. Dorsey, on September 2, 1855, opened the abdomen of a farmer, forty years of age, who had long suffered with violent pain in the region of the spleen. This organ was enlarged and had contracted abnormal adhesions, which the operator broke down, with the effect of restoring the man to health. Such a procedure was a much more remarkable one thirty years ago than it would be now.

As the entire spleen has been removed because of disease or displacement, or both in combination, some sixty-two times; and the proportion of cures is decidedly on the increase in latter years, we can readily afford to confine the record to an enumeration of the cases known to have been of a legitimate character. The leukæmic spleen is the most hazardous to remove, and if the leucocythæmia is very decided the operation is always fatal. A simple hypertrophic spleen, recent or congenital, is less dangerous to exsect, and the displaced or "wandering" spleen the least. But in all the operations the risks from hemorrhage and shock are very great, and patients are liable to die in collapse in a few hours. In traumatic cases there is much less risk in the removal of the organ, and the records of the past are decidedly encouraging to the operator.

PLASMODIUM MALARIÆ.

THE facts concerning the plasmodium, or, as Osler proposes to call it, the hæmatomonas malariæ, are such as to convince the most sceptical investigator that its relations with the malarial fevers, if not those of cause and effect, are certainly of a most intimate nature. It was in a spirit of scientific incredulity that the observer just mentioned began the researches which ended in his conversion to the views of Laveran. It seemed, says he, "so improbable, and so contrary to all past experience, that flagellate organisms should occur in the blood. The work of the past six months has taught me a lesson on the folly of a scepticism based on theoretical conception, and of preconceived notions drawn from a limited experience." Marchiafava and Celli, who are now among the strongest supporters of the doctrine that the plasmodium is an animal parasite, at first opposed the views of Laveran and Richard, and contended that the hyaline bodies within the red corpuscles were neither more nor less than a conversion of their hæmoglobin into melanin.

One of the latest contributions to this subject is that of COUNCILMAN, of Johns Hopkins University, who, in an address recently delivered before the Pathological Society of Philadelphia, not only reiterated his belief in the plasmodium, but announced, with reference to it, further facts of interest, the results of his continued study of malarial blood.

The significance of these facts is so great that it is unnecessary to refer to the corroborative work of others.

Several independent, thoroughly trained workers, in different quarters of the globe, using, in their researches, the best lenses of the best opticians, have arrived at the following conclusions: 1. In the blood of malarial subjects, an organism is invariably found, which organism is absent in all other conditions. 2. With improvement in the condition of the patient, the parasite disappears or remains in but one of its polymorphic forms, the pigmented crescent. 3. Quinia, the universal specific for malarial poisoning, is fatal to this parasite; so much so that it is a *sine qua non* in the search for it, that the patient shall not have recently taken this drug.

What more is needed to complete the circle of this discovery? But one thing, from a scientific point of view, although, from a purely clinical standpoint, its absence is not conspicuous. It is the cultivation of the organism in a pure state outside of the body and the production of malarial fever by its introduction into the blood of a healthy individual. Attempts to effect these objects have thus far proved unsuccessful.

In a recent communication to the Royal Academy of Medicine of Rome, Marchiafava and Celli call attention to certain differences in the structure of the plasmodium which appear to depend upon the influence of season. Thus, in spring and summer the pigmented forms, in autumn and winter the unpigmented, are more commonly present. This observation had been already made by Golgi. In fatal cases, in which the cerebral vessels contain quantities of the plasmodium, the presence or absence of pigment, in accordance with the season of the year, is said to be quite evident. The statement that the segmentation of the intracellular pigmented bodies occurs shortly before a chill, has been confirmed by Councilman. After the destruction of the corpuscles, these bodies, now of oval shape, escape, and, according to the Italian observers just mentioned, penetrate into the interior of other red corpuscles, but this last statement appears to depend rather upon inference than direct observation.

The blood changes of malarial poisoning, to which this brief reference has been made, are open to the inspection of any one who has the proper optical apparatus and the requisite skill to use it. Their presence is admitted by all, but their parasitic nature is denied by a few. For example, Mosso claims to have produced in the blood of the dog, by injecting it into the peritoneum of another animal—a fowl—all the changes ascribed to the plasmodium, and Tommasi-Crudeli, who adopts his views, triumphantly declares that, in future, these alterations will be attributed to a *pseudoplasmodium*. On the other hand, Marchiafava and Celli, who have repeated Mosso's experiments, maintain that but for his unfamiliarity with the alterations of malarial blood, he would not affirm their identity with those of his experiments.

Considering the great amount of labor that has been recently bestowed upon the study of malarial blood, and the careful drawings that have been made of the phenomena, both intra- and extra-corpuscular, observed in it, the bare statement of Tommasi-Crudeli, that such processes are *necrobiosis*, as he terms them, are not uncommon in other diseases, such as typhus (typhoid (?)) and scarlet fevers and pernicious anæmia, will not go far in the way of refutation. His criticism, however, that attention has been too exclusively centred upon malarial blood, may appear well taken until the reflection arises that but for this very concentration the changes in it would not have been observed.

Dr. T. Mitchell Prudden is in charge of the new laboratory of the College of Physicians and Surgeons, of New York, and is conducting a systematic study of the bacteria contained in the Hudson River ice, so much of which is consumed in New York and vicinity. He first personally visited the ice fields and took samples of water and ice to the extent of 300. He finds in a cubic centimetre of melted ice an average of 2033 living bacteria. The snow-ice has many more of them than the transparent block-ice. In the former kind of ice he has discovered as many as 12,000 to the centimetre. Dr. Prudden holds that the State Board of Health should have an active supervision over the ice harvest with the power to prohibit the business in localities that are too suspiciously close to large cities that discharge their sewage into the river.

Another blow at American industry may be constructed from a recent "warning to the public," by the police authorities of Berlin. From the official advertisement, it appears that, under the name of "Warner's Safe Cure," a brown liquid in bottles of about a pint capacity has been recommended as a remedy in kidney affections, and sold at the rate of four marks, or about a dollar, per bottle. Examination, it is stated, shows that the remedy consists essentially of "American wintergreen" (chimaphila?), and its value is, at most, two marks a bottle. This is an indorsement rather different from those familiar to our newspaper readers, signed by aldermen, clergymen, and cabinet ministers, but quite as instructive in its own way.

The capital punishment Committee of New York State, appointed a year ago, has made a report to the Governor in favor of electricity as a means of judicial execution instead of hanging. Among the many projects laid before the Committee was one from a Parisian mechanic, who has devised a chair in which the spinal column of the condemned can be instantaneously broken.

At the Eastern District Hospital, of Brooklyn, N. Y., about a month ago, a man who had been injured about the head and brought in by the police, died from erysipelas. The verdict of the coroner's jury censured the Hospital management on the score of inadequate attention. Suit has been brought, in the name of a young daughter of the deceased, against the institution and against the directors individually, for damages for the loss of her parent. The party bringing suit against the directors claims that, if this death can be shown to be due to want of proper care and attendance on the part of the medical staff, the directors can be made jointly and severally liable.

A bill has been introduced into the New York State Legislature making the Health Officer of the port a salaried official at $10,000 per annum. The present receipts from fees are generally quoted at about five times that amount.

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, December 28, 1887.

The President, J. Solis-Cohen, M.D., in the Chair.

Dr. Charles Meigs Wilson read a paper on

THE TECHNIQUE OF OÖPHORECTOMY.

He desired to call attention to those methods which have received the stamp of approval of the surgeons who have thus far had the best results in abdominal surgery. The methods detailed below are the *common* property of the medical profession, evolved by the experience of many operators. Some the author first saw used in England and in Germany, others are the result of American ingenuity, and all are of great importance in the production of good results after operating.

Preparation of the patient.—The urine should be carefully examined, in order to see that it is free from albumen. Neglect of this rule has doubtless oftentimes been the cause of the patient's death. The gastro-intestinal canal should be in state of healthy function, and the day preceding the operation all portions of the intestine should be thoroughly emptied. This is best secured by the administration of some gentle laxative, such as the compound liquorice powder, in one or two drachm doses; or, if there be torpidity of the liver, by the administration of one-twelfth of a grain of calomel every hour until the bowels are opened; care, however, being taken in both cases not to purge the patient, and not to set up any excessive peristalsis. On the morning of the operation, the rectum should be emptied by an enema, and in order to prevent the accumulation of gas in the intestines, and to avoid gaseous distention of the intestines, it is generally best to put into the laxative enema administered a little turpentine emulsified with the white of an egg. This, as a rule, relieves the intestines of any accumulation of gas present in them, and at the same time is not irritating.

The patient should have, on the morning of the operation, a hot bath, which will add to her comfort and remove any sebaceous matter on her abdomen; it is best to have the patient sponged with alcohol after the bath. Also, on the morning of the operation, the patient should abstain from taking food, unless it be a cup of strong coffee or a little milk and lime-water. The administration of this food should always precede the time of operation by three or four hours. Above all, it is necessary that the patient have a chance to recuperate her strength and prepare for the mental and physical ordeal of the operation by having a rest in bed of at least three days before the operation, and this is especially important if the patient has come on a long journey and is fatigued with travelling.

The operation.—The room for the operation should, when possible, have walls and floors which can be thoroughly cleaned and disinfected, in order that the operation may be conducted in an aseptic atmosphere. An operating-table of plain wood, painted, resembling in size and shape the ordinary kitchen table, is all that is necessary. One or two stands of light construction, and a chair for the assistant who holds the patient's limbs, are all the furniture required. A large can containing distilled water and an alcohol lamp or gas burner under it so as to maintain the heat of the water at a fixed temperature, and a tube running from the can to the table, so that at any time during the operation the whole operative field can be flooded, should also be in the room. The sponges are used over and over again until the sponge fibre commences to show evidences of disintegration. These are always of the finest quality and for the most part those which are known as potter's sponges, or thin, flat sponges. For the first time, they are prepared as follows:

All of the dust is first beaten out of them. They are then immersed in a fifteen per cent. solution of hydrochloric acid for forty-eight hours. They are next thoroughly washed until all the acid is removed from their interstices. Then they are placed for half an hour in a solution of permanganate of potassium, 180 grains to 5 pints of water. This is done in order to bleach them. The hydrochloric acid solution is for the purpose of removing any mineral matter that may be in their meshes. They are again washed in running water and placed in a solution consisting of ten ounces of the hyposulphite of sodium, five ounces of hydrochloric acid, and sixty-eight ounces of water. They are allowed to remain in this solution for a period of from two to four hours until thoroughly bleached. They are next thrown into troughs of running water, where they are allowed to remain for several hours. Afterward they are placed in jars containing solution of bichloride of mercury (1 : 1000) and hermetically sealed until the time of operation. After an operation they are washed out in warm water, then soaked in a solution of sodium carbonate half an ounce to a pint of water for three or four hours, then rewashed in warm water and put back in the 1 : 1000 bichloride solution ready for use again. The instruments are all nickel-plated, with the exception of the cutting edges. They are prepared by being first scrubbed with glycerine soap and then immersed for several minutes in boiling hot water. They are then laid upon towels which have pre-

viously been immersed in the solution of the bichloride of mercury (1 : 1000) and thoroughly dried by superheated steam. They are then ready for use. The needles are kept in a five per cent. solution of carbolized oil. The ligatures and sutures are kept immersed in a solution of bichloride of mercury (1 : 500). They are always washed in distilled water immediately before being used. For suturing the abdominal wall silkworm-gut has been found most satisfactory, clamped and held in position by perforated shot. For ligatures twisted Chinese silk has been found to be the best.

The temperature of the operating-room should be about 75°. It is best to cover all portions of the patient's body with light blankets, with the exception of that portion of the abdomen involved in the seat of operation. An assistant sits at the foot of the operating table, and receives and holds the patient's limbs, passes the catheter just before the operation, and, when necessary, with the finger in the vagina, lifts ovary, tube, or pedicle up into the abdominal wound, as the operator may desire. A trusted assistant takes charge of the anæsthetic, and does nothing else. The chief assistant stands on the left side of the patient, ready to give immediate aid to the operator.

Immediately preceding the operation, the patient's abdomen is wiped off with a little ether, in order to remove any greasy matter that may be present upon the abdominal wall, and is then washed with the bichloride solution (1 : 1000), and carefully dried, especial care being taken to see that all the little folds about the umbilicus are perfectly clean. If there be an abundance of suprapubic hair, sufficient is removed to give a chance for extending the incision downward if necessary. The operator having satisfied himself that the patient is sufficiently anæsthetized—and by sufficient is meant that she is anæsthetized to the surgical degree—the abdomen is opened with a few rapid strokes of the knife, without the use of the director.

The operator can readily judge of the depth of the abdominal wall, and really no care is required until the subperitoneal fat is reached. The abdomen is opened in the median line, care being taken to strike the linea alba if possible, so as not to open the sheath of the recti muscles. If the operator fails to strike the linea alba, no time is lost in dissection in order to reach it; but if he misses it, the abdomen is opened if need be, through the rectus muscle. The rule with reference to the incision best to be followed is to make it as small as is compatible with the removal of the ovary or of the growth. Where oöphorectomy is performed, an incision one and one-half or two inches in length is amply sufficient. On the contrary, where an ovarian cystoma is to be removed, and the tumor is a large one, or, perchance, semi-solid, or where the adhesions are numerous, it is a great deal better to enlarge the incision in order that the growth can be readily reached, rather than to attempt its removal without knowing exactly what we are doing, and without having room enough to raise it up through the abdominal wound.

No care is taken to prevent the blood from the wound in the abdominal wall escaping into the peritoneal cavity, and although it is always best to avoid allowing the contents of a cyst getting into the abdominal cavity, it is thought best to complete the operation rapidly, rather than to avoid the escape of the cyst contents into the abdominal cavity. If, however, we are dealing with a pus tube then, of course, the greatest care must be used to avoid the escape of the pus into the peritoneal cavity, owing to rupture of the tube wall. The pedicle is transfixed with an aneurism needle, the penetrating arm of which is at right angles to the handle, and tied with stout, twisted Chinese silk. The loop of the ligature carried through the pedicle is held as the needle is withdrawn, and divided; each half of the pedicle is tied, and then the whole pedicle is tied with the remaining parts of one of the ligatures. The pedicle is severed close to the ligature, care being taken, however, to leave sufficient of the pedicle to prevent the ligature from slipping. An important precaution to take to avoid secondary hemorrhage, is to hold the pedicle with the Martin forceps for a few moments and then, if there be no evidence of hemorrhage, it is dropped back into the peritoneal cavity. Where there is any tendency to hemorrhage from the pedicle, it is lightly touched with the flat button of the Paquelin cautery. Where the ovary is bound down by adhesions, and there is oozing from those which have been torn asunder, they are lightly touched with the finger, which has been rubbed against a piece of the perchloride of iron.

The abdominal cavity is then invariably flooded for about five minutes with a stream of distilled water at a temperature of 100° F. It is surprising to see how, when a patient is profoundly shocked, this intraperitoneal irrigation with hot water will immediately restore the equilibrium of the pulse and rally the patient from the shock. In operating, care should always be taken not to handle the ovary or the meso-salpinx any more than is absolutely necessary, because, as has been frequently noted, the patient's respiration becomes embarrassed, and oftentimes temporarily ceases during the time that the ovary is in the grasp of the operator's fingers. Where there is a cyst of any size, its contents are aspirated with Mears's trocar; but where the cyst is small, we prefer to enlarge the abdominal wound, rather than to delay the operation by evacuating the contents of the cyst with the aspirator.

The toilet of the peritoneum.—First, as noted above, the peritoneal cavity is thoroughly irrigated with distilled water at a temperature of 100° F. The patient is then turned on her side and all the water allowed to drain out that will. She is then again turned upon the back and the peritoneal cavity carefully sponged, the intestines and mesentery being held out of the way with one hand while with the other the operator carries the sponge attached to a bayoneted sponge-holder, first into the retro-vaginal portion of the peritoneal cavity and then into both iliac fossæ. The sponging is continued until all shreads of coagulated blood are removed and until, when the sponge is brought up, only a pale pinkish fluid escapes when the sponge is squeezed.

When we are sure that all hemorrhage has ceased within the peritoneal cavity, the intestines, if any have been left out of the abdominal cavity, are carefully replaced and the mesentery is folded over them. If necessary to lift loops of intestine out of the abdominal cavity, they should be carefully wrapped in soft towels kept moist and at a temperature of 100° F. Upon the mesentery is placed a thin, flat potter's sponge which extends half an inch or more around all portions of the wound. This is placed there in order to absorb any blood which may escape from the needle punctures. Its centre is

grasped by a hæmostatic forceps in order to facilitate its removal after the sutures have all been introduced. A strong, stout needle threaded with a loop of catgut or Chinese silk, in order to snare the silkworm-gut, is used in the introduction of the sutures. The sutures are all introduced from within outward in order to avoid wounding the intestines with the point of the needle, and the free ends of each suture are held in the bight of the hæmostatic forceps. When the sutures are all introduced, the flat sponge is removed and the central suture is first tightened. It is found that, as a rule, this makes a neater approximation of the edges of the wound. The sutures are fastened with perforated shot. The abdomen is carefully washed off with the solution of the bichloride of mercury (1 : 1000), immediately after the wound is closed. There is then poured over the surface of the wound a liberal quantity of Keith's dressing (twelve per cent. solution of carbolic acid in glycerine). Over this are laid five or six thicknesses of Lister's gauze and over the first thickness of the Lister's gauze (the one nearest the wound surface) is dusted a liberal quantity of pulverized iodoform or equal portions of iodoform and boric acid. Over the Lister's gauze is then placed a thick wad of bichloride wool—that is, wool that has been wet with a solution of bichloride of mercury (1 : 1000) and thoroughly dried. Over this dressing is applied a bandage of opera flannel fastened with safety pins.

After-treatment.—For the first twelve hours after operation, the patient eats absolutely nothing. If, at the end of that time, the patient has rallied from her shock, and there is no hyperpyrexia or other symptoms of evil import, we commence to feed the patient with weak tea, ice-cold, giving two or three drachms every hour. This we have found by experience to be the best way of quenching thirst and furnishing gentle stimulation without overtaxing the stomach or producing nausea or emesis. At the end of twenty-four hours we commence the administration of food. This is preferably milk, if the patient will take it and the stomach retain it. If the stomach be irritable, we give koumiss or matzoon in place of milk. Unless the stomach rebels, the use of the milk is continued in half-ounce doses with a little lime-water, and after a few hours it is alternated with beef or chicken tea; on the fourth day, if the patient is doing well, we commence the administration of animal broths and soft food.

The dressing is never changed unless symptoms arise leading us to suppose there is something wrong with the wound, or trouble within the peritoneal cavity. The sutures are removed on the seventh or eighth day. Drainage is never employed, unless we have reason to fear tissue necrosis as the result of traumatism of the operation, or unless we fear hemorrhage into the peritoneal cavity. If symptoms arise which indicate danger, it is a very easy thing to open the lower angle of the wound, and insert a drainage tube; where a drainage tube is used, glass is the preferable form. Great care must be taken to see that the mouth of the tube is thoroughly closed by a little tuft of the bichloride wool. When it is necessary to remove any fluid contained in the drainage tube, it is best done with the long uterine syringe, and after the removal of any fluid it is well to pour along the sides of the drainage tube a few drops of Keith's solution of carbolic acid and glycerine. As a rule, the patient is kept in the hospital for a week after the sutures are removed, and is enjoined from travelling any distance until a month has elapsed from the date of operation. The bowels are moved, as a rule, upon the sixth day, preferably by a gentle saline. Recently we have found Rubinat water the best for this purpose, giving a third of a tumblerful as a dose.

Great care should be taken by the operator to know exactly how many hæmostatic forceps, instruments, and sponges, are present in the room prior to the operation. It is the duty of the nurse to count over the instruments and have the count verified by an assistant both before and after the operation, in order that the operator may avoid the distressing accident which has happened of leaving a hæmostatic forceps or sponge within the abdominal cavity.

The operation may be performed at any time, with the exception of the menstrual period, and five days before and five days after it.

Complications arising in the after-treatment.—A majority of the cases that die after oöphorectomy perish from sepsis. Where proper care is taken in the preparation and management of the operation to have everything about the patient, including the atmosphere of the operating-room, the patient's body and clothing, the instruments, the dressings, and, above all, the conduct of the operation in aseptic condition, experience has shown that an extremely small per cent. of patients die from this cause. Careful attention to the rules described in this paper will do a great deal to prevent trouble of a septic nature after the operation. Cleanliness is the desideratum, and this is not by any means attained by the use of antiseptic agents. Indeed, the best results have been obtained, not with the use of carbolic acid or corrosive sublimate, but by the use of distilled or plain boiled water. Personally, he believes that the use of carbolic acid is never justifiable, for it can never be used in solutions sufficiently strong to possess aseptic properties without subjecting the patient to the danger of carbolic acid poisoning. Where, however, septicæmia does present itself it is best combated by reopening the abdominal wound and irrigating the peritoneal cavity with hot water. The septic hyperpyrexia is best reduced by the administration of antipyrin, and when once the temperature is gotten within the safety line it is best kept there by the administration of quinia. In desperate cases good results in the reduction of high temperature may be hoped for from the ice-cap. Stimulus must be freely given, and opium or chloral in sufficient doses to control the nervous disturbance which is nearly always present. Where it is necessary to give opium or chloral it is best to give by the rectum, saving the stomach for the administration of food and stimulus.

Peritonitis following operation is generally septic in character; it is best subjugated by the use of salines. Shock after the operation requires the same plan of treatment employed in treating shock after any other operation. The usual means employed are external warmth and the hypodermatic administration of cardiac stimulants, as soon as the patient can swallow a few spoonfuls of hot coffee, will generally be found the best means to counteract the shock.

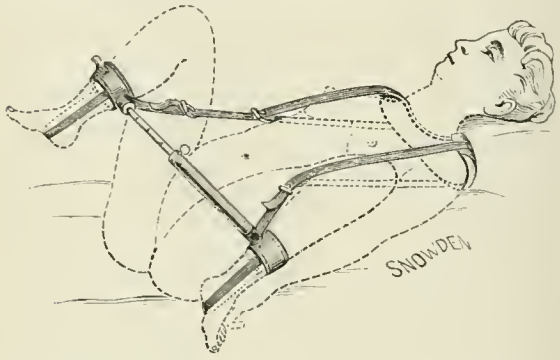
The limitations of oöphorectomy.—Dr. Wilson believes the operation is justifiable for the relief of ovarian pain, otherwise uncontrollable; for the artificial establishment of the menopause in cases of uterine fibromata character-

ized by rapidity of growth and exhaustive hemorrhage and in which all other means have been tried unsuccessfully; for the cure of those cases of hystero-epilepsy which have well-defined menstrual exacerbations and which have failed to yield to all other plans of treatment; and finally for those cases (which abound in every hospital for the insane) in which the mania or mental aberration is evidently dependent upon, or caused by, the act of ovulation. Indiscriminate, or what may be called hit or miss spaying, cannot receive too severe condemnation.

Dr. W. W. Keen reported

A MODIFICATION OF THE "PERINEUM DISTENDER" TO AVOID ITS INTERFERENCE WITH RESPIRATION.

In the frequent use of the "Perineal Distender," he has found the strap which passes under the nape of the neck very objectionable. This strap flexes the legs, and supports their weight. While doing so the weight of the legs pulls the head and neck strongly forward, and thus often seriously embarrasses the respiration.



To avoid this, he has had the wooden shoulder-piece of the old Day's apparatus for fracture of the clavicle slightly shortened, and finds it answers admirably. Under its loops, over each shoulder, two straps are passed with a buckle turned wrong side foremost at one end. The other free end, after passing through this buckle in the armpit, then is buckled to the cross-piece between the legs. By this means the pressure is brought on the shoulders instead of the neck, and respiration is entirely unimpeded.

He has also had two straps attached at right angles to the straps for the legs. By this means the leg-straps can be secured above the calf as usual or at the ankle. In this last position the new straps, by passing under the foot-soles, more completely flex the legs, and get the feet out of the way of the operator.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, December 8, 1887.

The President, Thomas M. Drysdale, M.D., in the Chair.

NEPHRECTOMY.

Dr. M. Price exhibited a kidney which he had removed in consequence of a perforating bullet wound. The patient, a young girl, was handling the weapon when it exploded, the ball entering in front on the right side and passing through the liver and kidney and burying itself in the spinal muscles. At the time of the operation, twenty-four hours later, the pulse was 150, temp. 103°, peritonitis had set in and the patient was in collapse. An incision, six inches long, was made, and arterial blood was seen escaping from the kidney, which it was thought best to remove. The liver wounds were dry and not oozing. Rapid improvement continued for nine days, but there has since been a rise of temperature, and on the nineteenth day the temperature is 100°, the pulse 108, and the patient is doing well.

Dr. B. F. Baer reported

A CASE OF SO-CALLED OVARIAN ABSCESS, SMALL SUPPURATING OVARIAN CYST,

occurring in a girl of seventeen years of age.

B. C. was sent to him on November 1, 1887. Puberty was established at eleven years of age, or, rather, she began to lose blood from the womb at that time, for she has never normally menstruated. As a rule, there would be a metrorrhagia every ten days to two weeks, sometimes lasting a whole week, but usually only three or four days. No serious trouble attended this flow except that she sometimes felt worn out, although it was not at any time excessive. At first after puberty the intervals were longer but gradually decreased until she was almost constantly flowing. She had never suffered much until last August, when she was taken suddenly with pain in the left ovarian region. The pain was sharp, cramp-like in character, and came on during the day, but she was not aware of any cause for it, such as over-exertion. The attack occurred a day or two after the cessation of one of these attacks of metrorrhagia. The pain increased in severity until it compelled her to go to bed, where she remained a week in great suffering under the care of her physician. She continued in bed four or five days after the pain ceased, from prostration and under advice. After this there was an interval of thirty days before the flow returned, the longest interval she had ever had. Then she began flowing again on October 2d, and continued to flow regularly every day for the next thirty days, at which time she first consulted him. Examination revealed the vagina rather patulous, cervix soft, and uterus occupying a position behind the symphysis pubis, where it was held by a tumor which occupied Douglas's pouch. The tumor extended as high as the superior strait and seemed about the size of a fœtal head. It was rather elastic, apparently circumscribed and fluctuating. He prescribed gallic acid for the metrorrhagia and advised rest. At the next visit he gave the patient ether and determined that the tumor was almost certainly of a cystic character and probably adherent to the posterior wall of the uterus and to the pelvic tissues generally. He advised its immediate removal because of the grave symptoms which it had no doubt produced, and because of the fear of its rupture and possibly fatal injury to the patient.

She entered Dr. Baer's private hospital on November 22d. Operation, November 24th. An incision two inches in length was made in the usual position, and two fingers introduced into the peritoneal cavity. He found the omentum adherent to the posterior wall of the uterus and upper surface of the tumor. This he dissected off and found a tumor the size of a large orange, slightly flattened, occupying a position behind the uterus, extending to the left. It was adherent everywhere and seemed

at first to be subperitoneal, but he soon discovered after beginning the separation of adhesions that his diagnosis of intraperitoneal tumor was correct. The adhesions were quite firm and it took ten minutes of careful manipulation to release entirely the tumor which he now brought up to the incision by placing two fingers under it, he next punctured it with a trocar and canula and drained away about six ounces of thick laudable pus, when it readily passed through the incision. The tumor was of the left ovary, the pedicle was very small and short, consisting of the ovarian mesentery and ligament. He could readily have removed it without removing the tube, so free was it from adhesions to that organ. Indeed, the tube seemed to be entirely free from disease. The opposite ovary and tube were perfectly healthy and were not removed. There was some hemorrhage, but it ceased after a little sponging and the abdominal incision was closed, drainage being considered unnecessary.

The patient complained of great pain after recovery from the anæsthetic, and it required three hypodermatics of morphia to relieve her. There was also violent reaction. Four hours after the operation the temperature was 102° and the pulse 148. This violent reaction was no doubt emotional, for as soon as the patient became quiet the temperature and pulse returned to the normal and did not again show the slightest indication of trouble. Her recovery was remarkably rapid and uneventful. She sat up on the eleventh and went home on the seventeenth day after operation.

Examination of the specimen showed it to be polycystic, the larger cyst cavity which contained the pus having a peculiar reddish, granular-looking lining membrane. At places papillary tufts were to be seen. The smaller cysts contained a clear fluid and had a smooth lining membrane. This case is interesting because of the early age of the patient, the early puberty, the frequent recurrence of the metrorrhagia, and the purulent character of the fluid contained in the cyst, the latter condition constituting what is commonly called ovarian abscess. This term is a misnomer. True ovarian abscess probably never occurs—that is, an inflammation in cellular tissue or stroma of the ovary which results in "a collection of pus surrounded by a wall of lymph," the surgical definition of abscess. When a pus cavity is found in an ovary Dr. Baer believes its origin can always be traced to a previously existing cystic degeneration of the ovary, the purulent formation being secondary.

DR. J. PRICE remarked that tubal disease may exist in virgins, the probable cause of infection being unclean hands and instruments of an examining physician. The small drainage tubes were introduced in London by Dr. Bantock, and were of seven different lengths. A dangerous rise of temperature certainly does at times arise in some cases from emotional causes, a good example of which, he thought, had occurred in New York, at the Woman's Hospital. A patient was operated on in one of the cottages, and was doing nicely; during convalescence she was moved into the hospital much against her will, her temperature arose immediately, and she died in a few hours.

DR. HIRST said that "emotional fever" is often observed after laparotomy. He had seen the temperature rise above 100° in an instant because he had told the nurse in the hearing of the patient that "the stitches were to be removed to-morrow." He had seen some very extraordinary cases of "emotional fever" in the puerperal state, having more than once seen the temperature rise suddenly to 104° in consequence of a fit of weeping. This phenomenon is not very uncommon in the Maternity Hospital, where the patients are for the most part young unmarried primiparæ.

DR. KELLY observed that instrumental infection of a healthy woman is a very real danger to which many victims have been sacrificed. He advised aspiration in all small cystic tumors before proceeding to their delivery at the incision. In this way a certain proportion of lives will be saved by avoiding the frequently inevitable rupture with an escape of poisonous contents amongst the intestines. A systematic use of the drainage tube is advisable, but not such tubes as are in common use. Dr. Dudley, of Chicago, uses a very delicate little tube which can be slipped in between the sutures and answers all purposes, especially used as he has long done, leaving in a piece of twisted absorbent cotton which carries everything up from the bottom of the tube by capillary attraction.

DR. DA COSTA remarked that he had used a tube with an outside diameter of only three-eighths of an inch four years ago, and did not think there was anything new about it as he had at that time bought it ready made from the shops.

DR. LONGAKER believed that many cases of diseased tubes are due to filthy instruments and careless manipulation. A case had come under his care of an unmarried woman of undoubted virtue, suffering from bilateral disease of the appendages. Her history was that of dysmenorrhœa for which the os had been incised. After this operation she was confined to bed for six months. Some months later she came into his hands, and was also seen in consultation by the late Dr. Albert H. Smith, who agreed in the diagnosis. The case passed out of his hands without operation. The conclusion that the operation was not done under perfect conditions is forced upon us, and also that by reason of this carelessness her condition was rendered worse than it had been.

DR. DRYSDALE, in reply to a question from Dr. Baer, said that often when the ovarian cells are crowded together the fluid will have the appearance of pus. The application of acetic acid will, however, always differentiate them from pus cells. Pus and ovarian cells can exist in the same fluid, but in cases where the pus cells become in excess the ovarian gradually disappear. A blow on the abdomen over the ovary has caused an inflammatory process which resulted in an ovarian abscess. Dr. W. L. Atlee had always drained after serious operations, but in his day tubes had not been introduced; he had used tents.

NEWS ITEMS.

The Improved Condition of the Crown Prince.—The *British Medical Journal* of January 7, 1888, writes as follows regarding the improved condition of the Crown Prince:

It is with profound satisfaction that we learn, on the highest authority, that the symptoms which caused so much alarm at the beginning of November have almost entirely disappeared. The growth in the subglottic region, which was then looked upon with such suspicion, has now shrunk to a fourth of its former size; the ulcer

on its surface has completely healed, and the submaxillary glands, which were enlarged and hardened, are now in a perfectly normal state. The little growth which recently showed itself on the left ventricular band (false vocal cord) sloughed away very soon after its formation, and the ulcerated surface left behind was nearly cicatrized when Sir Morell Mackenzie left San Remo. The Prince is now quite free from the slight, but constant feeling of discomfort about the larynx from which he had suffered since the beginning of last year, and his face has lost the somewhat waxen pallor which struck so many observers when His Imperial Highness was in England. We are able to state that, in the opinion of Sir Morell Mackenzie, the appearances in the Crown Prince's throat are now quite compatible with the more severe form of chronic laryngitis.

In illustration of this, it may be interesting to quote some remarks from his work on *Diseases of the Throat*, vol. i. p. 288, where it is stated that "in addition to congestive swelling of the mucosa and submucosa, there occurs in some rare cases an organic thickening or hypertrophy of the soft structures." It is also said there that "nodular excrescences the result of chronic inflammation are often met with," presumably in the rare cases just alluded to. These words were written eight years ago, and the case of the Crown Prince would seem to be a perfect example of the morbid condition which they describe. In addition to the chronic inflammatory process, there is no doubt that perichondritis is also present. In speaking of this affection, Sir Morell Mackenzie (*op. cit.*, p. 391) has called attention to the frequency of "impaired action of one or both of the vocal cords;" and it may be remembered that in the case of the Crown Prince the action of the left cord has been defective for many months past.

Whilst, however, there is now good ground for hoping that the disease may be of the comparatively favorable character here indicated, it would be foolish to allow ourselves to take too optimistic a view of the situation. The possibility of the affection being after all malignant, in spite of present appearances to the contrary, must not be too hastily dismissed; and, on the other hand, it should not be forgotten that even the milder complaint, toward which the symptoms seem now more or less definitely to point, is a serious one both in itself and in its possible consequences.

Gleditschia Triacanthos Again.—Pharmacist Metz, Instructor in Practical Pharmacy at Tulane University, New Orleans, has recently made careful experiments with the leaves of the honey locust, endeavoring to extract the alkaloid. He obtained from Messrs. Goodman and Seward, who first obtained the leaves, a description of the localities and trees from which the first leaves were taken, and endeavored to find the original sources. He failed, however, to find any trace of the investigations of Goodman and Seward; the substance which he obtained from leaves taken in the original localities and from the honey locust trees failed to exhibit the slightest anæsthetic or active properties; and his investigations confirmed his opinion that the alleged discovery was a hoax.—*American Druggist*, January, 1888.

Disinfection at the New Orleans Quarantine.—*Science* of December 30, 1887, describes the methods in use at the New Orleans Quarantine as follows: The methods practised by Dr. Holt are very thorough, and in their application, a tugboat, fitted up with all the necessary machinery, is employed. The bedding of the vessel, together with cushions, mattresses, carpets, rugs, etc., is removed from the ship to a commodious building in close proximity to the disinfecting wharf, where they are treated by moist heat at a temperature of not less than 230° F. During this process of steaming, every article is perceived to be saturated and intensely hot, the steam freely penetrating to the interior of mattresses, double blankets, etc.; but so great is the heat in the texture of the fabrics as to expel immediately all moisture upon drawing the racks and exposure to the open air. Shirts and collars instantly assume the crisp dryness they possessed before exposure, losing the musty smell of long packing in a trunk. Silks, laces, and the most delicate woollen goods show no signs of injury whatever from the treatment. Articles of leather, rubber, and whalebone would be injured by the heat, and are, therefore, disinfected with the bichloride of mercury solution. The time required to charge the chamber with apparel for disinfection is thirty minutes; time required for action of most heat, twenty minutes; for removal of articles, fifteen minutes—a total of sixty-five minutes.

Appointment.—Dr. V. P. Gibney, Professor of Orthopædic Surgery in the New York Polyclinic, has been appointed Surgeon-in-Chief in the Hospital for Ruptured and Crippled, New York.

Prize Awarded.—Dr. Daniel Longaker has been awarded the prize of $25 offered by the Philadelphia Clinical Society for the best paper read at its meetings in 1886.

A Spanish Congress for Gynecology.—A congress is to be held at Madrid, under the auspices of the Spanish Gynecological Society, in April or May, 1888. It will consist of three sections: obstetrics, gynecology, and "paidopatia," which, we presume, means diseases of children. The general and sectional work of the Congress will occupy eight days.—*Medical Press.*

A Successful Splenectomy.—From the *British Medical Journal* of recent date we learn that an enlarged spleen was removed in London on Dec. 5th by Sir Spencer Wells. The solid portion, now at the College of Surgeons, weighed one pound fourteen ounces, after a great deal of blood had drained from it. The patient was an unmarried lady, aged twenty-four. The wound healed by first intention, and she was so well on December 21st that she is expected to return to her country home before the end of the year. No doubt the case will be published, or brought before one of the Societies for full discussion.

Diphtheria in Straw Heaps.—A writer in the *British Medical Journal* of December 17, 1887, remarks that the works of Klebs, Ferrand, and others show that straw and manure heaps play a considerable part in propagating diphtheria. An army surgeon has tried to prove by statistics to what extent these statements are reliable. He has collected the following facts. In the French army diphtheria causes three times as many deaths in cavalry regiments as in the infantry. This affection is

most prevalent in the cavalry barracks in Paris which are in the vicinity of stables belonging to Paris omnibus companies and near a large depot for manure. In the German army the same proportion exists, there being three more deaths from diphtheria in the cavalry regiments than in the infantry. In the Austro-Hungarian army diphtheria is rare, and is principally met with in the cavalry regiments. MM. Emmerich and Chaveau consider that the diphtheria of birds is identical with that of human beings, also that fowls and pigeons may be the means of introducing diphtheria germs into any hospital. This theory, however, is still unproven.

The Medical Department of the University of Giessen.—Buildings for the accommodation of clinics for medicine, gynecology, and pathology are in process of erection at this university. At the suggestion of Professors Ludwig and Riegel, a clinic of 80 beds and an asylum of 200 or 300 beds are to be added.

The Gonococcus in Court.—From the *Medical Press* we learn that some little time ago, in Belgium, a man was accused of the rape of a little girl. On the clothing of the accused and on that of the alleged victim spots of pus were found, and handed over for examination to a physician and a pharmaceutist of the first class. These experts declared the pus to be gonorrhœal, whereupon the defending counsel demanded proof of the presence of gonococci. Dr. Castiaux, Professor of Forsenic Medicine at Lille, was, therefore, called upon to make a fresh examination of the spots with the object of determining the existence or non-existence of microörganisms. Dr. Lober, who took part in the examination, made pure cultivations of the pus on various media, and finally on sweetened and peptonized agar, and by this means was enabled to confirm the gonorrhœal nature of the pus.

A New Hospital at Vichy.—An extensive hospital has been recently constructed and opened at Vichy, at a cost of between $300,000 and $400,000. It comprises a hospital for the people living in the vicinity; a ward for the aged; a ward for orphans; a thermal hospital, devoted to treatment of those who visit Vichy to take the waters; a wing for military patients, and an official pavilion, with a chapel, and other auxiliary buildings.

Disinfecting Stations.—The Department of the Seine has ordered the erection of a station for compulsory disinfection in each of the eight districts under its jurisdiction.

The Number of Physicians in Prussia.—The statistics of Prussian physicians on April 1, 1887, showed 8228 physicians in civil life, and 813 physicians in military service. The distribution of civilians was fairly proportionate to the population.

The Successful Cremation of two bodies was performed in the new crematories constructed in Père-La-Chase by the city of Paris, on December 15th.

Sleep and the Gastric Juice.—Dr. P. V. Burjinski, of Professor Manassein's Clinic in St. Petersburg, having enlisted the services in the cause of science of some students and other persons who managed to overcome the natural repugnance most people feel to the passage of even a soft œsophageal tube, has made some investigations on the effect of sleep upon the acidity of the gastric juice. He estimated this acidity by means of a standard solution of soda, and he tested it also for hydrochloric acid. The best test for the latter he found to be floroglucin-vanillin. As, however, this cannot be used when there is any yellow color in the fluid to be tested, the subjects of the experiments were fed on the whites of eggs, all the yolks being carefully put aside. The result of numerous tests showed that during the night the gastric juice is less acid than during the day. Care was, of course, taken that the conditions regarding food were the same during the night as during the day. Dr. Burjinski also found that the amount of acidity varied directly with the amount of hydrochloric acid present.—*Lancet*, December 24, 1887.

Chemical Changes of the Blood in Tuberculosis.—A year ago Dr. Ernst Freund, a pupil of Professor Ernst Ludwig, published the results of his chemical researches on tuberculosis in the *Wiener medicinische Jahrbücher*, 1886. He stated that he had been able to prepare from the blood, as well as from the tuberculous growths of the organs of twenty-five tuberculous cases examined, an organic body belonging to the group of carbohydrates, exhibiting all the reactions peculiar to cellulose—viz., it was insoluble in the ordinary indifferent solvents, but readily soluble in a solution of cupric hydroxide in ammonia; it was resistant to the action of Schulze's mixture of nitric acid and chlorate of potassium; when dissolved in concentrated sulphuric acid, it was converted into sugar by boiling with diluted sulphuric acid, and when treated with nitric acid, ether, and alcohol, a collodion-like body was obtained; it assumed a blue color when treated with iodine in presence of concentrated sulphuric acid or of a concentrated solution of chloride of zinc, and a blue color by adding α-naphthol to its solution in concentrated sulphuric acid. For the sake of control the blood and the normal or pathological organs of thirty other cases were examined, but no trace of cellulose could be found in them. Freund's statements on the occurrence of cellulose in tuberculosis have been confirmed by recent researches carried out by Dr. Kabrhel in the laboratory of Professor Hobaszewski, of Prague. In continuing his researches on the chemical basis of tubercular disposition, Dr. Freund made examinations of ashes of the blood, and found that there is a considerable increase of the potassium salts in the blood of tuberculous persons, while the sodium salts and phosphoric acid are reduced in quantity. The ash of normal blood contains, according to the researches of Jarisch, 25.31 to 26.62 per cent. of potash, 23.7 to 26.13 per cent. of soda, and 8 to 8.96 per cent. of anhydride of phosphoric acid; the ash of the blood of tuberculous persons was found by Freund to contain 29.84 to 37.57 per cent. (miliary tuberculosis) of potash, 12.85 to 18.26 per cent. of soda, and 4.3 to 6.79 per cent. of anhydride of phosphoric acid. The urine in these cases, however, showed no increase of potash. On these results Dr. Freund based a series of therapeutical experiments, which are being carried out in the wards of Dr. Langer. The leading idea of these experiments is to withdraw carbonate of potash from the body and to introduce sodium salts. For this purpose, large doses of phosphoric acid and phosphate of potash, soda, and lime, followed

by carbonate and bicarbonate of soda and chloride of sodium, are used. Dr. Freund maintains that some of the cases treated in this way improved, especially those affected with chronic tuberculosis.

The Influence of Sensations on One Another.—Under this head Dr. Urbanschitsch, of Vienna, reports some curious experiments, the value of which must be left to future research to decide. His general conclusion is, that the excitation of one sense-organ increases the acuteness of the others. If a disk be regarded at such a distance that its color is indistinct, the hearing of a sound will bring out the color. The beating of a watch is heard more clearly with the eyes open than with the eyes closed. Red and green increase auditory perceptions; blue and yellow weaken them. The fact that we listen to music with our eyes closed is due to other reasons, and also to the fact that the *ensemble* appears best when the tones are not at their clearest. Smell, taste, and touch are open to the same influence. Red and green increase the sensitiveness of each of these senses; yellow and blue weaken their sensitiveness. Touch and temperature have a reciprocal influence. If one tickles the skin and plunges it into warm water, the tickling ceases; if into cold water, the tickling brings out the feeling of cold. These observations are regarded as showing the same reinforcing action between sensations as has been shown to exist between motions, and as offering a mode of explanation of those curious associations between colors and sounds so persistent in some minds.—*Science*, December 30, 1887.

The Dangers of Travel in Spain.—The *Lancet* of December 17, 1887, relates the following recent adventure of an English physician: Last week Dr. Middleton, of Scarborough, who was on his way to Tangier, halted with his companions at Cordova. Leaving his fellow travellers at the hotel, Dr. Middleton, accompanied as a guide by a gypsy, visited the cathedral, than which there are few more attractive buildings in the world, for when Cordova was the capital of the Moorish realm in Spain it was the great mosque of the city. He had begun to descend the narrow winding staircase of the tower, followed by the gypsy, when suddenly the latter attacked him from behind, nearly strangling him with one arm, while with the other hand he took two dollars from his intended victim's pocket, and wrenched his walking stick away. Dr. Middleton then drew his revolver and fired two shots over his shoulder, one of which entered the gypsy's mouth, the other taking a downward course through his body. The shots were fatal, and, covered with blood, Dr. Middleton descended and gave notice of the occurrence to the police, who, on their arrival at the scene of the tragedy, found the dead thief still holding in his hand the stick and the two dollars. Dr. Middleton was arrested, but has since been released on bail. The gypsy had, it appears, the worst of reputations, and a most significant fact is that he was companion two years ago to an Englishman visiting the cathedral tower, who was found dead at its foot. The case was then supposed to be one of suicide, but, looked at in the light of Dr. Middleton's experience, it is now viewed differently.

The Death of Gustav Theodore Fechner, Professor of Experimental Physics at Leipsic, is announced. The chief work of his life was upon psycho-physics, and around his theory and writings has sprung up a considerable literature on the subject.

Professor Arthur Christiani.—The death of this well-known scientist of the Physiological Institute at Berlin, is announced. He was a great authority on the physiological action of electricity, on the physiology of the nervous system, and on that of the sense of hearing.

Carl Langer von Edenberg.—This distinguished anatomist, Professor in the University of Vienna, died on December 8, 1887, aged sixty-eight. He was the pupil and assistant of Hyrtl, whom he succeeded. Among his numerous works on descriptive anatomy the greatest are his text-book of *Systematic and Topographical Anatomy* and *Six Contributions to the Study of the Joints.*

Dr. Bernutz. Physician to the Charité, died recently at Sedan. He contributed an extensive series of articles upon gynecological and obstetrical subjects, his best known book being a clinical work on gynecology, in two volumes, which he edited with Goupil.

Dr. Samuel A. Purdy died in New York city, January 12th, in the seventy-sixth year of his age. He was a member of an old colonial family, which has been well represented in regular medicine. He was a graduate in 1834 from the College of Physicians and Surgeons, New York, and one of the earlier members of the Academy of Medicine.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM JANUARY 10 TO JANUARY 16, 1888.

BARNETT, RICHARDS, *Captain and Assistant Surgeon.*—Ordered from further duty in Division of the Atlantic, to duty at Fort Riley, Kansas, to take effect at the expiration of his present sick leave.—*S. O. 5, A. G. O.*, January 7, 1888.

TESSON, LOUIS S., *Captain and Assistant Surgeon.*—Relieved from duty at Headquarters of the Division of the Missouri and as Examiner of Recruits at Chicago, Illinois, and ordered for duty as Post Surgeon at Watervliet Arsenal, N. Y., relieving Captain Henry G. Burton, Assistant Surgeon.—*S. O. 5, A. G. O.*, January 7, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING JANUARY 14, 1888.

PURVIANCE, GEORGE, *Surgeon.*—To proceed to Detroit, Mich., as Inspector of Unserviceable Property, January 11, 1888.

AUSTIN, H. W., *Surgeon.*—When relieved to proceed to Chicago, Ill., and assume charge of the Service, January 12, 1888.

GASSAWAY, J. M., *Surgeon.*—Leave of absence extended fifteen days, January 10, 1888.

GOLDSBOROUGH, C. B., *Surgeon.*—When relieved to proceed to New Orleans, La., and assume charge of the Service, January 12, 1888.

IRWIN, FAIRFAX, *Surgeon.*—To proceed to Boston, Mass., and assume charge of the Service, January 12, 1888.

CARTER, H. R., *Passed Assistant Surgeon.*—When relieved to proceed to Ship Island Quarantine, Miss., and assume temporary charge of the Service, January 12, 1888.

CARRINGTON, P. M., *Assistant Surgeon.*—Granted leave of absence for thirty days, January 10, 1888.

ORIGINAL LECTURES.

RECENT ADVANCES IN THE SURGERY OF THE BRAIN AND ITS COVERINGS.[1]

BY CHARLES B. NANCREDE, M.D.,

SENIOR SURGEON TO THE EPISCOPAL HOSPITAL, SURGEON TO THE JEFFERSON MEDICAL COLLEGE HOSPITAL, LATE LECTURER ON SURGERY DARTMOUTH MEDICAL COLLEGE, ETC.

MR. PRESIDENT AND FELLOWS OF THE ACADEMY OF SURGERY: In casting about in my mind for a topic worthy of the consideration of this learned body, it occurred to me that an inquiry into the recent advances made in the surgery of the brain and its coverings, might prove both interesting and profitable.

I have endeavored, by repeated eliminations, to prepare a condensed account of all the essential advances made since I completed my monograph upon "Injuries of the Head," which in the delivery shall not exceed the time allotted me by custom; this will necessitate the omission of many interesting details. While repudiating all intention to dogmatise, I shall endeavor to formulate *provisionally* some general rules for our guidance in practice, and on the witness-stand. Some of the alleged advances will, upon examination, resolve themselves into mere confirmations of much older tentative propositions. Statistics will not be introduced, except when necessary to prove the truth of assertions apparently opposed to previous experience, nor will details and histories of cases be interpolated, except when needful to illustrate a principle or elucidate some obscure point.

It has recently been shown[2] that, while of unusual occurrence, the smallest scalp-wound, if it become infected, may by progression of the septic inflammation lead to periostitis, purulent ostitis, osteophlebitis, encephalitis; or, again, from the periosteum the infective process may, by continuity of tissue, through osteophlebitis, initiate thrombosis of the cerebral sinuses with consequent pyæmia.[3] Suppose a recent head injury just brought into the hospital, how should we proceed? Do not carelessly pass the forefinger through the filthy, blood-matted hair, and explore at once the depths of the wound, to ascertain its nature, as is too commonly the rule, but carefully shave the scalp, scrub it with nail-brush, soap and water, remove all fatty matter with ether, or a mixture of turpentine and alcohol, completing the disinfection by a thorough irrigation with mercuric bichloride solution. Only now should the wound be examined, when, if either bone or periosteum be found injured, such incisions are indicated as will give free access to the deeper parts, which must next be cleansed. All small, loose fragments of the external table are to be removed; if large, after disinfection, they should be perforated and sutured in place with catgut, leaving sufficient space between the fragments for drainage; all sharp edges should be smoothed off, and, if deemed necessary, catgut drains can be placed between the osseous fragments. Should there be simply a *clean* fissure, let it alone; but if a *soiled* one, cut it out with a chisel and thoroughly disinfect.[1]

By the light thrown by experiment, and confirmed by recent experience, we must entirely revise our conclusions as to the dangers of trephining, *per se*, or of converting a simple fracture into a compound one. Roberts's propositions would now meet with general acceptance.[2] Certainly, our increased knowledge as to the risks of the late cerebral mischief, too often entailed by the erroneous opinion that trephining is only indicated when symptoms of *compression* are present, serves to teach more strongly that which I, in common with Gross, Briggs, Gunn, Roberts, and others, have insisted upon, viz., preventive trephining. Wagner has recently presented a more cogent reason for immediate interference in these words: "The entrance of foreign bodies and injuries from unclean objects, therefore, indicate the use of the trephine," because "it is of far greater importance to prevent the infection of the intracranial tissues, than to relieve the brain from pressure;"[3] even a hair caught in a fissure will certainly produce infection if not promptly removed, as has been proved in more than one instance.[4] The value of what may appear to some, unnecessary precautions, is proved, when we reflect that when immediately put in practice the mortality was only 1.23; whereas, when twenty-four hours or more had elapsed before treatment was instituted, the death-rate was 33.33 per cent.[5]

Special precautions must be observed when both walls of the frontal sinus are broken. Most thorough disinfection of the sinus should precede perforation of its posterior wall, and at the conclusion of the operation, the cavity must be carefully tamponed with iodoform gauze, remembering that symptoms of secondary compression may result from swelling of the tampon, by imbibition of wound fluids. The orbital margin should be unhesitatingly resected, if necessary to remove infected materials or foreign bodies.

I would, therefore, lay down the proposition: that in the present state of science, the surgeon who neglects to resort to the foregoing precautions is derelict in his duty.

A triumphant demonstration of the value of attention to details is given by Wagner, all of whose cases of fractured base who survived the first twenty-four to forty-eight hours—23 in number—recovered. Similar results can only be attained by attention to the following precautions, in addition to those already mentioned:

[1] Annual Oration, delivered before the Philadelphia Academy of Surgery, January 3, 1888.

[2] W. Wagner: Königshütte, Volkmann's Sammlung klinische Vorträge, Nos. 271, 272, Chirurg., Nos. 85, April 20, 1886.

[3] Horsley's case, Med. Press and Circular, 1886, N. S., 495.

[1] Hippocratic experience revived, since this was advised by the Father of Medicine, although upon a different theory.

[2] August and September numbers, Annals of Surgery, 1885.

[3] W. Wagner, op. cit. [4] Wagner, op. cit.

[5] Wagner, op. cit.

The external auditory canal of the ear traversed by the line of fracture, must be most cautiously and effectively disinfected, filled with iodoform, and plugged with antiseptic gauze. If the ethmoid be fractured, iodoform should be dusted or insufflated into the upper part of the nasal cavities. Extensive fractures with alarming nervous symptoms, due to extravasation of blood or inflammatory exudates, do not contraindicate operation in fractures of the vault, or accessible portions of the base; since, if such cases are recoverable at all, this desired end is more likely to be attained by the effective drainage and asepsis secured by operative interference.

Bearing in mind the immediate risks of encephalitis and the future ones of epilepsy and insanity there can be but one opinion as to the advisability of trephining for all varieties of accessible cranial fractures, provided it can be shown that the operation, *per se*, is not a dangerous one. Undoubtedly, under the old regime, the mortality of the operation was 10.69; but is this true with an improved technique? Certainly not; for after eliminating from Amidon's[1] tables certain cases where no trephining was done, many which were not treated strictly aseptically, verifying the remainder and adding others, Seydel[2] has tabulated 61 cases of operations for epilepsy, neoplasms, etc., which would indicate that strict aseptic methods reduce the mortality of trephining, *per se*, to 1.60 per cent., although it must not be overlooked that injuries to the brain, its membranes or vessels, by careless operating, will increase this death-rate.

If the mortality be so low for operations where no recent injury exists, how much more imperative should it now be to trephine immediately in recent compound and even simple, markedly depressed vault fractures, except in young children.

Are there any new principles deducible from recent experience which should govern the technique of trephining?

At once the question of drainage confronts us: Shall it be capillary or by tube? Upon a nice discrimination of cases will, I believe, depend success in practice.

For trephining in fractures, epilepsy, or insanity, in which no lesion of the dura mater exists, catgut, and catgut only seems indicated.

Where large portions of bone have been removed and replaced in toto, no other method of drainage is possible.

With lesions of the dura mater which are reparable by suture,[3] the same kind of drain is indicated, except when a brain tumor has been removed.

Wounds of the dura mater which cannot be sutured indicate tube-drainage, or, better, Horsely's method.

Trephining done for intracranial abscess calls for the use of the tube very gradually shortened, with the strictest watching of the case for some weeks after final withdrawal.

If the first perforation made does not effectually drain a blood or pus cavity within the membranes or brain, when the patient is in *the recumbent position*, either a second opening at the most dependent point should be made and through-drainage instituted, or, better still in many cases, the first button of bone should be replaced after removing a small segment of its periphery, while the second opening is utilized for the drain.

What shall be done with the bone fragments which have been removed? If they are contaminated with foreign material this should be carefully removed even to paring with the bone chisel,[1] when the fragments must be placed in a warm antiseptic solution until needed. If the surgeon fears to reimplant them in bulk, the fragments can be carefully minced up with the chisel and dusted over the membranes.

I would call attention to the peculiar value of this expedient as a preventive of the formation of a hernia cerebri, where such injuries to the dura mater exist as to forbid suturing, or where this membrane seems likely secondarily to give way. The experience of Macewen, Weir, and others incontestably proves not only the feasibility but the advantages of a resort to this procedure.

The general principles governing the treatment of compound skull-fractures are strictly applicable to gunshot wounds, so far as the bone lesions are concerned. Wharton's tables so conclusively show the ultimate evils of the retention of a foreign body in the brain, that if the operation can be done without fatal injury to the encephalon, balls should always be removed, since, even primarily, such injuries are certain to be followed by suppurative inflammation, which too commonly is of the diffused form, when death is inevitable.

The most superficial glance at the histories of recoveries after apparently hopeless brain injuries, shows that the result was due to free drainage, as in the famous tamping-iron case, and one of extensive shotgun disorganization of the anterior fourth of the left hemisphere, which I reported to this Society some two years ago.

The principle of free drainage then, rather than the mere removal of the foreign body, is the guiding principle of the modern treatment, although, to effect perfect drainage, both theoretically and practically, the course of the ball must be followed throughout and disinfected, when the missile being accessible, and capable years hence of producing serious trouble, should be removed.

Heretofore, the main difficulty has been a safe method of search for the ball. Fluhrer[2] has, however, enunciated a new principle capable of revolutionizing practice, if found reliable, viz., the use of a peculiar probe which is allowed to pass along the track of the ball by its own *gravity*, which is so slight as to be absolutely incapable of penetrating the brain substance. The metal forming the probe is aluminum. This instrument should never be curved if it can be avoided, but when bent, the other extremity should be curved in the opposite direction; this is imperative since it is the only means of indicating what course the instrument is taking.

How, then, should we proceed in a case of ball-wound of the brain? After the usual antiseptic preliminaries and incisions, all loose bone fragments must be removed and the opening enlarged if necessary. The patient's head must be then placed so that the track of the ball is as nearly vertical as possible, when the probe, gently introduced into the brain-opening, is to be allowed to *gravitate* along the ball-track. Fluhrer[3] has shown that when

[2] New York Med. Journal, March 28, 1885.

[3] E. M. Moore has also observed the same. Trans. Amer. Surg. Association, vol. iii. p. 91.

the whole cerebral mass has been traversed without penetration of the opposite wall of the cranium, the ball usually rebounds at an angle equalling that of incidence, and becomes imbedded in the brain, about one inch above, below, outward, or inward, according to the direction of the ball. If the probe shows this complete perforation to have occurred, a large counter-opening is to be made, the ball extracted, and the dressing completed as will be indicated for non-perforating ball-wounds.

Suppose, however, that the ball is imbedded in one hemisphere? Place the head as before, and locate the ball with the gravity-probe, then, if no vital parts intervene, pass the probe onward through the brain-substance till it strikes the skull; trephine at this point, cause the probe to emerge, attach two long threads of aseptic silk to the anterior extremity of the instrument, which must now be withdrawn posteriorly, leaving the threads in the wound. With the probe passed through the wound of entrance, measure the distance of the ball from the surface. Now draw through the wound track by means of one of the silk threads passed with a needle through the end and out by the eye, a No. 3 English catheter with straightened stylet, and turn the head so as to have it as nearly in a horizontal plane as possible. A pair of long, slender, double-toothed, self-closing cervix forceps, notched with a file behind the teeth so as to hold a loop of fine aseptic silk must be passed to the previously measured depth—again verified after passing the guide—alongside the catheter by means of the silk loop: if the loop does not play freely over the guide, let guide and forceps move together. Should the ball not be found on one side of the guide, the forceps must be removed and reintroduced on the opposite side, above or below. When grasped, ball, forceps, and guide must be withdrawn together. By means of the remaining thread left in the ball-track, a drainage tube is carried through the whole course of the wound and an antiseptic dressing applied. Drainage must be effected after the same manner for perforating wounds.

Suppose the ball is not found, thorough drainage is afforded for all inflammatory products, and the chances of recovery are enhanced. In a recent case seen with Dr. Heyl at the Episcopal Hospital, failing to find the ball, I introduced a drainage tube about one inch into the brain-substance which evacuated considerable purulent fluid for one week, when it became displaced: recovery ensued without a single bad symptom, although cerebral mischief had evidently commenced before the operation, some twenty-four hours after injury.

In view of these and numerous other facts, active, but cautious interference, is not only now warranted, but demanded, for gunshot wounds of the head.

What should our attitude be with regard to that too rarely recognized condition, osteophlebitis from contusion or disease? When the "puffy tumor of Pott"[1] exists, the bone should be trephined or otherwise freely removed, the diseased area thoroughly disinfected, and strict asepsis maintained. This course, I contend, is correct, not because pus will always be found between the dura mater and bone—for this often does *not* exist—but because *osteophlebitis* is present which frequently leads to fatal septicæmia or pyæmia. That under the most unfavorable circumstances success is still attainable in cases of this nature, which have resulted even in thrombosis of the lateral sinus and septic embolism of the heart and lung, is proved by a recent operation of Horsley's, the disease originating, as is usually the case, from old middle-ear disease.[1]

When considering what should be done for malignant growths of the skull, two most important questions press for solution. If a patient be primarily attacked with malignant disease of the cranial bones, or the subjacent osseous tissue become secondarily involved by extension from the overlying soft parts, shall any operation be done? If an operation be decided upon, what are the prospects of relief, are they merely temporary or permanent?

If it can be shown that the necessary operative interference in such cases is not specially dangerous to life, the first question is answered in the affirmative.

As a typical instance of the successful removal of a primary growth take that of Gussenbauer,[2] who, for a sarcoma of the frontal bone, after reflecting one-half of the forehead as a flap, removed with chisel and forceps the frontal bone over an area measuring three by three and one-half inches, detached the growth at one point from the dura mater, and at the end of two years no recurrence was detectable.

Again, Paully[3] reports the following case illustrative of the impunity with which these operations can be done. In March, 1882, he removed a portion of the frontal bone for a fibrous sarcoma. The wound healed, but at the end of two months the growth returned in situ. Curretting now failing to benefit, six months later the "frontal bone was removed from the root of the nose to the zygoma and up to the hair line; in one month the wound was quite healed. Five months later an enlarged gland behind the angle of the jaw was suggestive of return."[4]

Still more corroborative of the slight danger attendant upon these operations when conducted on strictly antiseptic principles, is a case of Krönlein's, which certainly teaches that in properly selected cases, malignant growths secondarily affecting the cranial vault, should be dealt with precisely upon the same general principles as govern operative treatment for similar neoplasms situated elsewhere, viz., early removal and with a free hand; if the latter part of this advice be not strictly adhered to, such operations had better not be attempted, for the danger to life is the same with no reasonable prospect of good accruing, if timidity gains the upper hand. Of course, the freedom with which surrounding parts should be removed must depend upon the importance to life or motility of the contiguous portions of the encephalon.

Krönlein, after three excisions and two free cauterizations of a carcinoma of the forehead, by another surgeon —*i. e.*, insufficient operations which were only provocative of return—successfully removed—so far as life was concerned—a cancerous ulcer, two and a half inches wide "extending from the root of the nose beyond the line of the hair." To get well outside of the disease area, he removed a piece of bone and dura mater about three-quarters of an inch in diameter, and in addition nearly

[1] Or other evidence of bone inflammation.

[4] Op. cit.

half an inch of the falx cerebri. Temporary benefit ensued, but a second operation becoming necessary two months later, the patient succumbed, but not then even until three months after this last operation.[1]

Although of no permanent benefit, does not such a result encourage us to demand for similar cases *early complete* operations? Death is inevitable sooner or later, and is it not worth while to run the comparatively small risk inherent to such operations, to achieve occasionally a permanent result?

Of fifteen cases done with full antiseptic precautions thirteen recovered from the operation and two died—one of air embolism, a preventable accident.[2] The dura mater was incised or portions excised in eight cases; in four operations the falx cerebri was cut; the longitudinal sinus was twice divided; and in as many instances portions of brain substance were removed. In all considerable bone was excised, and in five the gap left measured transversely three inches. These fifteen operations were done upon twelve patients, in all but two the growth occupying the frontal region. Recurrence took place in only one instance before healing and rapid recidives, all told, in four cases.[3] Such a showing, I believe, warrants the following statement.

That when malignant, or other tumors clinically dangerous to life, attack the accessible bones forming the brain-case, early and thorough removal is indicated, provided the proper completion of the operation does not necessitate the removal of portions of the encephalon essential to life or, perhaps, to progression.

A much larger measure of success awaits those who now operate for that very fatal complication, intracranial hemorrhage, than formerly obtained. The statement of Hutchinson[4] is no longer true, that "the modern annals of surgery do not contain any cases in which life has been saved by trephining for this state of things."

Cecherelli,[5] Krönlein, Weiseman, and others have presented an overwhelming mass of statistical and practical evidence of the advantages of operative interference.[6]

The first question to be settled is, Shall an anæsthetic be given? After Godlee's experience, I for one, think that chloroform is certainly contraindicated, while I also believe that ether is prejudicial and is usually unnecessary from the semi- or completely comatose condition of these cases.

Again, where should the skull be perforated in those cases where neither fracture nor external injury exists.

Since the middle meningeal artery is usually the source of hemorrhage, unless specially contraindicated, the trephine had better be placed[7] from an inch and a quarter to an inch and a half behind the external angular process of the frontal bone on a horizontal line drawn around the skull, at the level of the upper margin of the orbit, parallel with "Reid's base line." Should this opening reveal neither clot nor a bleeding vessel, a second opening on the same line just below the parietal boss must be made.[1]

In one successful case of Krönlein's these two openings were made and a drainage tube passed through both.

The same surgeon correctly diagnosticated the presence of clot in four cases, in two successfully operating and removing it, but failing to make the second opening in the other two, the patients died, post-mortem examination showing that a second perforation would have been successful.

Wetherle[2] also reports a fatal case owing to failure to make this second opening. After removal of the clot by forceps and antiseptic irrigation, unless all bleeding has ceased, if in the dura mater the vessels must be secured by ligatures passed with a curved needle, by a red-hot knitting needle, or acupressure will suffice;[3] or, again, especially for the vessels of the pia mater, serre-fines left until spontaneously separated may be tried.[4]

I, in common with others, have been compelled to resort to antiseptic tampons. Unless through-drainage is clearly necessary, the first bone-button had better be replaced when two openings have been made, and the more dependent one utilized for drainage. If after trephining severe secondary hemorrhage occurs, Jacobson recommends first the application of a freezing mixture over the dressings, then placing the patient in the upright posture, next compression of the common carotid, and finally, if this fails, ligation of the same vessel.

Weiseman's latest statistics[5] show that of 147 cases treated by the expectant plan 131 died, or about nine-tenths, while of 110 operated upon, only 36 died, or about one-third. Moreover, it must be borne in mind that in the majority of those who died, the extravasation was not reached, and, of course, not removed; had this been done the mortality would, undoubtedly, have been less.

This is a far better showing than my statistics collated in 1883, and is unquestionably due to the prevalence of antiseptic methods. Indeed, Krönlein maintains that this operation, aseptically performed, is perfectly safe, death resulting simply from complications unconnected with the operation.

The chief advance in the treatment of brain abscess is the making of a second bone opening at the most dependent portion of the cavity, if the first trephine cut is not favorably situated for drainage, after which the first opening can be closed by its own bone-button, notched on one side to prevent accumulation of pus and wound-secretions. Mr. Barker prefers a silver to a rubber tube,

[3] A pellet of wax, or plugging the canal, when it exists, with a match are other means.

[4] This was suggested by Fluhrer, op. cit.

[5] Ueber die Indicationen zur Trepanationen mit besonderer Berücksichtigung, etc., Deutsche Zeitschrift f Chirurg., Bd. xxi. und xxii., 1885. I would here acknowledge my indebtedness for the facts from these papers to leading articles in THE MEDICAL NEWS of December 26, 1885, and May 8, 1886.

as being both easier of introduction and retention. Fenger and Lee's[1] case teaches how gradually the tube must be shortened, and how long after its final removal it is wise to watch a case. Both upon anatomical and pathological grounds, I think that it is usually best to trephine for intracranial suppuration following chronic ear disease, one and one-fourth inches above, and the same distance behind the centre of the cartilaginous external auditory meatus. Through the perforation thus made the pus must be sought by passing an aspirator needle downward, inward, and slightly forward, toward the petrous bone. When the pus is found, the needle track can be enlarged by a Volkmann's spoon,[2] and a drainage tube introduced.[3] The point mentioned has been selected because pus is more often found in these cases in the temporo-sphenoidal lobe than in the cerebellum or elsewhere, for the tympanic roof is the thinnest portion of the bone, while more vessels pass from the tympanum and along the squamoso-petrosal suture to the dura mater than from the posterior portion of the petrous bone. In all cases, however, the foramen for the mastoid vein should be examined, before perforating the bone, because "if there be inflammation on the posterior aspect of the petrous bone, it can hardly reach the cerebellum without forming a layer of pus under the dura mater of the lateral sinus. If this is so the pus will escape by the mastoid foramen if the latter be exposed."[4] When this condition is found, a spot beneath and slightly posterior to the mastoid foramen, below the inferior curved line of the occipital bone, will be the proper place to explore for cerebellar abscess following chronic middle ear trouble.[5] I have given Mr. Barker's points for perforation in preference to those of Mr. Caird and others, because they are safer anatomically, since they are less apt to injure the meningeal artery, the pus can be evacuated through a comparatively callous portion of the brain, and nine-tenths of these abscesses in the temporo-sphenoidal lobe occupy a space three-fourths of an inch in diameter, whose centre is one and a half inches above and behind the centre of the cartilaginous external auditory meatus.[6]

In this connection let me give the result of Spitzka's researches as to the use of exploratory aspiration. "Experience with human and experimental pathology teaches that exploratory needles should never be introduced into the internal capsule, the contiguous ganglia or the lateral ventricles, merely for exploratory purposes, unaided by positive clinical evidence of the location of the disease; but no hesitation need be felt in the puncturing of the brain for hydrocephalus."

"Accessible neoplasms of the brain, which have resisted medicinal treatment, and which continue to grow and threaten life, should be removed, for the reason that they are generally single, seldom have secondary deposits, are surrounded by an inflammatory zone of demarcation, and *always* kill by pressure."[7] These words of Amidon's admirably express the present position of surgery with regard to brain tumors. But can every case which resists medicinal treatment be confidently turned over to the surgeon with the idea that whether the case recovers or not, at least the tumor can be found, and the operation can be completed.

W. Hale White's[1] analysis of 100 brain tumors examined after death, shows how rarely such operations are feasible. Thus:

Of 45 tubercular tumors, 7 possibly could, and 3 certainly could have been removed.

Of 24 gliomata, perhaps 6, and certainly 4 might have been operated on.

2 glio-sarcoma would have been inoperable.

Of 10 sarcomata, only 1 could have been removed.

Of 5 carcinomata none ought to have been attacked, because of secondary growths or multiplicity of tumors.

5 gummata could all have been reached, but would have been, of course, amenable to medicinal treatment.

Of 4 cysts 1 could have been reached.

Of 3 tumors whose nature was doubtful, 2 would have been fit for the knife.

1 lymphoma from general contamination would have been inoperable; and finally,

1 myxoma would have been accessible.

Closely scrutinized, of this 100 cases only 12 were certainly operable, and 6 more could possibly have been successfully attacked.[2]

While unable to give statistics of completed operations for brain tumors, when we recall Horsley's remarkable series, Durante's and Keen's successes, is it at all doubtful that the mortality will greatly diminish in the near future? A rapid review of Horsley's methods will show why his success exceeds that of others.

The head must be carefully shaved the day before operation, washed thoroughly with soft soap, followed by ether, the situation of the growth localized and marked on the scalp, the head covered with lint wet with 1 : 20 carbolic lotion, and oil silk with a layer of cotton bandaged over all. A purgative should be exhibited the night previous to, with an enema on, the morning of operation.

About one hour previous to the administration of the anæsthetic a hypodermatic injection of one-quarter of a grain of morphia should be given, and, unless the heart be diseased, chloroform is preferable to ether, since ether produces more cerebral excitement. The object of administering morphia is twofold—*i. e.*, less chloroform is needed, and from Schäfer and Horsley's experiments, this drug contracts the arterioles of the central nervous system,[3] thus lessening hemorrhage.

The chief risk being septic encephalitis, the spray may be used solely as a cleanser of the atmosphere.

All incisions of the soft parts should be vertical to the skull, and include all the layers at one stroke, except the periosteum. A single flap should be thus raised, its outline being a shallow curve, in order not to divide collateral vessels, and so planned as to avoid the main scalp arteries. These indications can readily be fulfilled without interference with drainage, since the patient will lie in the supine position.

[1] Transactions American Surg. Association, vol. iii. pp. 65, et. seq.

[2] If preferred, a pair of dressing forceps can be first carried down along the needle as a guide, and withdrawn, after Hilton's method, but the spoon seems better.

[3] Barker: Macewen, Schomdorff, Trunkenbord, Greenfield, report cases; all recovered

[2] The figures differ from those given by the author, but careful addition of the numbers given in the text sum up as I have given above.

[3] When tapping for hydrocephalus I have resorted to this method with apparent benefit.

The periosteum must now be incised, raised, and reflected; if more bone has to be removed than was originally planned the periosteum must be carefully dissected back off each new portion.

Two large trephine cuts—Horsley recommends that the crown of the instrument be of the diameter of two inches—should be made at the two extremes of the bone area to be removed, when the intervening bridge can be partially sawn through with a Heys saw, and the division completed with the bone forceps. Almost as rapid, and a far safer plan—since the bone over brain-tumors is often not thicker than cardboard—is to remove the bone with the rongeur, as modified by W. Barton Hopkins, after one or more preliminary trephine cuts of the ordinary size. In many instances the bone fragments had better be replaced, and accordingly should at once be placed and kept in a warm antiseptic solution.

Next the dura mater must be cut around four-fifths of the osseous orifice, one-eighth of an inch from the bone, so as to leave room for stitching; start the incision with a scalpel, but complete it with blunt-pointed scissors. Any arteries seen lying in the line of the proposed dural incision must be first tied, by passing ligatures through the dura, beneath and around the vessels, with a curved needle before incising the membrane.

The brain being now exposed, note first if it bulges into the wound—*i. e.*, is the intracranial tension increased? Next look for a yellowish tinge or possibly lividity, which will denote a tumor in the corona radiata beneath the cortex. Now closely scrutinize the vessels and perivascular lymphatics, noting especially "any yellowish-white patches in the walls of the latter indicating old mischief." Finally ascertain whether the brain has undergone any alterations in density, although in most subcortical tumors the diagnosis can only be made certain by an exploratory incision.

Hemorrhage has been much dreaded in the removal of brain tumors, but the fear is unfounded, for the arteries and especially the arterioles, which are chiefly concerned in such operations, run perpendicular to the cerebral surface and sponge-pressure soon checks all bleeding. Should this fail, ligature of the larger vessels must be tried, but if their walls are too fragile[1] to stand ligation, forcipressure is alone available. In one case at least, Weir's,[2] continuous pressure with iodoform-gauze packing failed to prevent fatal secondary, or rather recurrent hemorrhage, and the operator declared that should a similar case occur in his practice he would leave one or more pressure-forceps on the bleeding vessels for from twenty-four to forty-eight hours. Fluhrer[3] has shown that the ligature often fails to hold on the vessels of the pia mater, and advises leaving Nunneley's artery-forceps on any bleeding points until the instruments separate of themselves. I recognized the advantage of this practice recently, when assisting Dr. Simes in a case of subdural hemorrhage proceeding from a wounded artery of the pia mater; here a small wire serre-fine was substituted for the pressure-forceps, and left *in situ* for days. As the cerebral arteries are terminal, avoid every vessel possible, this end being often attainable by lifting them out of the sulci between the convolutions, and after removing the subjacent brain, replacing the pia mater. Horsley thinks that if any thrombosis should occur in these vessels it would only be temporary. If one of the large venous sinuses be wounded during an operation, its ligation is a perfectly safe procedure, healing occurring as in veins, and collateral vessels enlarging alongside of the occluded channel. Sponge-implantation or antiseptic tampons will always temporarily and often permanently[1] arrest the bleeding from a wounded sinus. The risk of air embolism is not imaginary, but can be obviated by keeping the head low and the wound well irrigated. When it is evident that a sinus must be wounded in a proposed operation it had better be primarily ligated as in a case of Küster's.[2]

Incisions into the brain must always be clean-cut, be vertical to the surface, and directed into the corona radiata, when necessary, so as to avoid damage to the fibres coming from other portions of the cortex, or those surrounding the seat of operation. The paths pursued by the fibres from the cortex must be kept constantly in mind when incising the brain, and where possible portions of each centre involved should be left, as under such circumstances the coarser movements of the part governed will often be retained.[3] Finally, it is absolutely essential to be thoroughly familiar with the encephalic blood supply to decide where to make the incisions, in order to have a full understanding as to what portions of the remainder of the organs certainly will be deprived of their blood supply, and what portions may possibly be rendered avascular.

When a portion of brain is excised, the underlying cerebral tissue soon bulges up almost to a level with the cortex while the cut edges evert, and if "less brain than bone is removed," protrusion—*i. e.*, an acute hernia cerebri forms. A persistence of this dangerous condition is prevented by the weight and primary union of the scalp-flap; the advantages afforded by the large one recommended are thus apparent.

After all oozing has been arrested by gentle sponge-pressure or ligatures, in my judgment the flap of dura mater, if the operative procedures have left it intact, should now be carefully sutured with chromic catgut to the margins of the membranous opening, leaving space for the easy passage of a drainage tube at the most dependent point. The scalp-flap should then be laid down and secured by stitches of medium silk placed one centimetre (about one-third of an inch) apart with horsehair sutures between.

When brain substance has been removed drainage should not be kept up more than twenty-four hours, because firm union must be secured within four or five days, and a certain degree of pressure should in the meantime be exercised upon the brain which tends to protrude, in order to avoid hernia of the organ. Again, there should be some protective between the brain and scalp in the form of soft—*i. e.*, non-inflammatory—con-

[1] Dr. W. W. Keen informs me he met with this difficulty, and succeeded by drawing the catgut only tight enough nearly to close the lumen of the vessels.

nective tissue. Briefly, all these desirable results are obtained by:

1. Placing a tube at the most dependent portion of the wound when the patient lies supine, for twenty-four hours only, to drain all blood and serum.

2. After twenty-four hours remove the tube and re-dress as at first antiseptically, making "firm but gentle pressure over the centre of the flap."

3. If on the third day pain and throbbing in the wound be complained of, and the flap, on exposing the wound, be found "distended in the centre the periphery being firmly united," undue collection of wound-fluids has taken place. If it appears probable that the pressure will break down the union of the flap, the track of the drainage tube must be gently opened up with a probe, and some of the pent up fluid let out; if the union seems safe to hold, let the accumulation alone, since after the evacuation of the fluid the advantages of supporting pressure are lost. The tension at most usually requires to be relieved but once. This liquid cushion, until absorbed, represses the tendency to hernia, promotes absorption by the meningeal lymphatics of all inflammatory exudates, thus favoring rapid union, and serves as a scaffolding for the formation of normal connective tissue which is formed within a few days, at least in the lower animals.

After from five to seven days boric acid, cotton, and collodion for support are better than the ordinary antiseptic dressing. The stitches can be removed any time after the first week.

Should a second operation become necessary, or a primary one for brain injuries which have resulted in scars of the cortex, especially those produced by traumatic losses of brain-substance, which have healed after free suppuration, great caution must be exercised, since the cicatrices often displace large vessels, and are traversed by veins of considerable size.

Encouraged by Horsley's success in excising brain-scars for epilepsy, Hughlings Jackson[1] has suggested the propriety of removing the seat of "the discharging lesion," in cases of the spontaneous variety, when the spasms begin "very locally, deliberately, and when the fits are often repeated."

The theoretical advantages of this suggestion have been essentially proved by the following case of Macewen's, which certainly seemed cured by the removal of the site of the discharging lesion,[2] as well as by one of Jackson's, operated on by Horsley.

A young man in perfect health, having received two years previously a skull injury, which in six weeks resulted in headache and epilepsy, came under Macewen's care, suffering from one hundred or more attacks per diem; in which, however, he never entirely lost consciousness. The muscular spasms were limited to the side opposite that of injury, at which point a slight depression was detected. Trephining here at once uncovered the brain, revealing an old rupture of the membranes. A small circumscribed area of non-suppurative inflammatory softening existed beneath the bone-opening. Although apparently thoroughly anæsthetized, the removal of the diseased tissue with a sharp spoon at once produced a violent convulsion. All pain and convulsions ceased after the operation.

In traumatic epilepsy, then, in addition to the removal of all depressed bone, cicatrices of the brain and membranes must be freely excised, including, if possible, the site of the discharging lesion.

Cysts should, after the same precautions as advised for cerebral tumors, be carefully curetted and drained, preferably by the tube, but recognizing the risk of hernia cerebri by this method of treatment.

For the successful therapeusis of hernia cerebri, it is requisite to place absolute confidence in the indications for treatment so plainly discernible after a careful study of the pathology of this affection. There are two principal and one subsidiary factors in the production of hernia cerebri. As has been said, the normal intracranial tension after incision of the membranes and removal of a portion of brain, suffices to cause cerebral protrusion, if less brain tissue than bone is removed. Hence, the removal of the support of the membranes and bone, plus increased tension are the chief causes, and, in consequence, anything favoring these conditions is to be avoided. What can increase intracranial tension? Manifestly only encephalitis, which is also productive of the subsidiary, but effective factor, softening of the cerebral tissues. How can we best prevent intracranial inflammation? By strict asepsis. But is this all that is essential? No; for the normal intracranial tension, as we have just seen, is almost efficient by itself, so that suturing of the damaged membranes must be done when possible. Where the suturing either cannot be done, or seems likely to fail, Horsley's modified drainage, to keep up due restraining pressure should be tried. Finally, I would make a tentative suggestion, grounded upon the treatment of a somewhat similar condition of the membranes of the spinal cord, viz., the suturing to the margins of the membranous defect, a thin slice of aseptic sponge; in other words, a sponge graft, which may serve, after infiltration with and organization of the contained white cells, as an effectual barrier against brain protrusion. Moreover, whenever possible, replacement of the bone fragments, either in toto, or after Macewen's plan, will in many cases afford the requisite amount of restraining pressure.

I would here call your attention to the steadily lessening mortality attendant upon the strict aseptic treatment, aided by gentle pressure, of hernia cerebri, and the avoidance of anything which will weaken the support of the layer of granulations, which forms, or tends to form, over the exterior of all brain protrusions, which is the sole barrier against further extrusion of the cranial contents, and which by its organization into contracting scar-tissue finally reduces the hernia.

The experience of the last four years has proven the truth of what I advanced years ago, that ligating, excising, and cauterizing these protrusions, while at times ending in recovery, is unscientific, because opposed to the indications derived from the pathology of the affection; and that such practices are attended by a rate of mortality far higher than that just advocated. The danger does not reside in the mere protrusion of brain-substance, but in the *encephalitis* which is the cause of the hernia, or is consequent upon it.

In conclusion, let me venture the prophecy, that those of my hearers who now consider much of what I have advanced to-night as far too heroic, will live to look upon my suggestions as mere matters of course, and as little to be reprobated as ovariotomy.

EXPERIMENTAL STUDIES ON THE CAUSATION OF TYPHOID FEVER, WITH SPECIAL REFERENCE TO THE OUTBREAK AT IRON MOUNTAIN, MICH.[1]

BY VICTOR C. VAUGHAN, M.D.,
AND
FREDERICK G. NOVY, M.S.,
OF ANN ARBOR, MICHIGAN.

LAST October, having heard of the prevalence of a severe epidemic of typhoid fever at Iron Mountain, Michigan, we requested Dr. G. B. Johnson, a physician of that place, to forward to us a sample of the drinking water used by families in which the disease had appeared. This request was immediately complied with, and we determined to make the most thorough tests possible. The ordinary sanitary analysis, which consists in the determination of free and albuminoid ammonia, chlorine, nitrates, and nitrites, we determined would be altogether inadequate. Besides, as we afterward learned, such an analysis had already been made by the competent chemists of the Chapin mine at Iron Mountain. The results of this analysis, together with those of other waters in the village, made by the same chemists, will be given further on.

After much deliberation, we determined to inoculate sterilized meat preparations and sterilized milk with the suspected water, and then to keep the material at or near the temperature of the human body for varying periods of time, and to ascertain whether or not there would be any poisons developed by the bacteria which were suspected of being in the water. The following are the details of the method:

A number of Erlenmeyer flasks of 400 c. c. capacity were thoroughly cleansed and rinsed with distilled water, then dried in an air-bath. When dry, they were tightly closed with plugs of cotton, and heated for two hours at 140°–150° C.

A litre of fresh milk was placed in a large flask, plugged with cotton, and heated in a Koch's steam sterilizing apparatus for over three hours. The flask was then taken out, and, while yet warm, its contents were transferred by means of a sterilized graduate and sterilized funnel, in portions of 130 c. c. each, to the above-mentioned sterilized, small flasks. The transfer was made as speedily as possible, and the flasks were immediately plugged with cotton, and capped with pieces of filter-paper, which were held in position by means of rubber bands. The flasks, thus prepared, were placed in the steam sterilizing apparatus, and heated for two hours. This was found to produce perfect sterilization.

One pound of lean beef was chopped up finely and treated with one litre of distilled water. The whole was set aside in a cool place for twenty-four hours, being occasionally well shaken. It was then filtered through cloth, the filtrate was diluted to one litre with distilled water, placed in a large beaker and heated almost to boiling. Then twenty-one grammes of peptone, and five grammes of pure sodium chloride were added. While still hot, the solution was carefully neutralized with sodium carbonate, then placed in the steam sterilizer and heated for two and one-half hours. After removal, and when cold, it was filtered through paper; the filtrate was made up to one litre with distilled water, placed in a large assay flask, plugged with cotton, and heated in the steam sterilizer for three hours. After cooling it was transferred to the sterilized flasks, which were plugged with cotton and heated for two hours in the steam sterilizer.

Nov. 9, 3 P. M. Some of these flasks were inoculated with Iron Mountain water; others with some water which we had received from Lansing, Mich., and which had been used by a family, some members of which suffered from typhoid fever; and one each of the milk and meat preparations was left without inoculation, and used as controls.

Two of the meat and two of the milk flasks were inoculated with 30 c. c., each, of the Iron Mountain water, and one meat and one milk flask with 50 c. c., each, of the same water. The same number of flasks, and the same amount of water were used with the Lansing water. Thus we had six flasks inoculated with the Iron Mountain water, six with the Lansing water, and two controls.

These flasks were then placed in a Koch's vegetation apparatus and kept at from 30°–38° C.

11th. Forty-seven and a half hours after the inoculations were made, four flasks, one containing meat preparation and Iron Mountain water; the second, milk and Iron Mountain water; the third, meat preparation and Lansing water; and the fourth, milk and Lansing water, were removed from the vegetation trough, and examined.

The meat preparation inoculated with Iron Mountain water had a strong, repulsive odor, showed an abundant, white bacterial growth, and was neutral in reaction. It was filtered, rendered feebly acid with hydrochloric acid, extracted with ether, then rendered alkaline with sodium carbonate, and extracted successively with ether, benzole, and amylic alcohol.

The acid ether extract was allowed to evaporate spontaneously, the residue was dissolved in alcohol, acidulated with dilute hydrochloric acid and evaporated on the water bath. The reddish residue was dissolved in water, filtered and tested for ptomaines. It gave no alkaloidal reactions, and contained no poison.

The alkaline ether extract, treated in the same manner as the acid extract, gave slight precipitates with phosphomolybdic acid and platinum chloride, but was also inert.

The alkaline benzole extract gave no alkaloidal reaction, and was free from poisonous properties.

The amylic alcohol extract gave slight precipitates, but if it contained any poison the amount was too small to have any effect upon animals.

[1] A Preliminary Report to the State Board of Health of Michigan.

After the above extractions had been made, the fluid was again rendered acid with dilute hydrochloric acid, and then evaporated in vacuo at 40° C. The residue was treated with absolute alcohol, filtered and again evaporated in vacuo, again taken up with absolute alcohol and now allowed to evaporate spontaneously. The final residue dissolved in water gave precipitates with many of the alkaloidal reagents, but showed no poisonous properties.

We were now convinced that no poison had yet developed in the meat preparation inoculated with the Iron Mountain water.

Similar examinations were made with the milk and Iron Mountain water, the meat preparation and Lansing water, and the milk and Lansing water, and similar results, so far at least as the failure to detect any poison is concerned, were reached. Indeed, the chemical reactions were marked by only slight variations. The bacterial growths were much more abundant in the Iron Mountain water inoculations than in the others.

16th, seven days after the inoculations were made, four flasks, similar to those previously examined, were removed from the vegetation apparatus, and their contents were submitted to analyses similar to those already detailed.

The meat preparation inoculated with the Iron Mountain water was strongly alkaline in reaction and gave off a marked amine odor. After being acidified with hydrochloric acid, it was evaporated on the water-bath, the residue was extracted with absolute alcohol and filtered. The filtrate gave a precipitate with an alcoholic solution of mercuric chloride, but the precipitate proved readily soluble in slight excess of the precipitant. The mercury was removed by precipitation with hydrogen sulphide and filtration. The filtrate was evaporated on a water-bath, leaving a syrupy residue with some crystals of sodium chloride. The syrup was poured off from the crystals, taken up with water, and a portion of it (only a few drops of the syrup) was injected by means of a hypodermatic syringe under the skin on the back of a cat. The temperature of the cat before the injection, taken with care and with a tested thermometer in the axilla, was 99.5°. The following is a record of the effect observed in the experiment:

EXPERIMENT I.—Temperature before the injection, 99.5°.
Time of injection, 3:14.
3:24. Temp. 100.2°.
3:44. Temp. 101.5°. The cat drinks a large quantity of water, although she had an abundant supply of milk, which had been within her reach during the day, and of which she had previously partaken. After drinking there is considerable retching, but no vomiting. The respirations are greatly accelerated and jerky. The pupils are dilated, but respond to light.
3:54. Temp. 101.8°.
4:19. Temp. 101.8°.
4:30. Temp. 101.5°.
The temperature was not again taken until the next morning, when it was found to be 99.5°. The animal seemed to have wholly recovered from any discomfort which it had suffered.

EXPERIMENT II.—Two days later a similar amount of the syrupy residue was administered to the same cat in the same manner.
Temperature before the injection, 99.5°
Time of injection, 4:30.
5:00. Temp. 102°.
The temperature was not taken again until next morning, when it was found to be 99.5°.

EXPERIMENT III.—A similar amount of the syrup was administered to another cat.
Temperature before the injection, 100°.
Time of injection, 3:33.
4:08. Temp. 101°.
4:33. Temp. 101°.
4:50. Temp. 101.6°.

EXPERIMENT IV.—*Dec. 1.* A much larger amount of the syrup than that used in the preceding experiments was injected under the skin on the back of a large Maltese cat.
Temperature before the injection, 99.5.°
Time of injection, 4:03.
4:19. Temp. 94°; marked salivation.
4:44. Temp. 98°; pupils are widely dilated. The cat vomits heavily and persistently.
5:30. Temp. 100°. The retching continues and a watery secretion flows from the mouth, nose, and eyes.
6:00. Temp. 100°. Seems in a stupor.
2d. 8:00 A.M. Temp. 103.4°. Stupor continues.
1:40 P.M. Temp. 103.4°. When touched on the abdomen the animal cries as if in pain.
4:20. Temp. 104.1°. The animal seems much excited and dashed through the door of the room once, though she had previously been very quiet.
3d. 9:15 A.M. Temp. 99.6°. Seems to be recovering, but still looks very haggard. Has eaten nothing since the injection.
1:40 P.M. Temp. 100.8°. Eats some meat.
4th. 8:50 A.M. Temp. 99.5°.
The cat was now killed with chloroform and careful examination made of the abdominal and thoracic organs. No abnormality could be found.

EXPERIMENT V.—Some of the syrup obtained from the milk which was inoculated with Iron Mountain water was injected under the skin on the back of cat. The temperature in this case was taken in the rectum.
Temperature before the injection, 102.5°.
Time of the injection, 3:55 P.M., *Dec. 9.*
4:40. Temp. 97.6°.
5:25. Temp. 100.9°.
10th. 9:05 A.M. Temp. 103.6°.
2:40 P.M. Temp. 102.4°.

Both the meat preparation and the milk, which had been inoculated with the Lansing water, were carried through the same chemical processes to which the Iron Mountain preparation had been submitted, but they yielded only traces of the syrupy residue, and these when injected into animals were without effect. These served as controls for the experiments already detailed, and showed that there was nothing in the meat preparation or milk themselves which could cause the effects observed. As further control, however, the sterilized meat preparation which had been prepared as a control, and which had remained in the vegetation trough for forty days at the temperature of the body without showing any bacterial growth, was treated in the same manner that the other preparations had been, and the alcoholic residue was injected into animals without producing any effect.

Evidently the syrupy residue, which was used in the above experiments, contains a poisonous ptomaine,

the special or characteristic production of the micro-organisms present in the Iron Mountain water; and if these are the germs of typhoid fever, this syrup contains the special poison of typhoid fever. In the intestines of a man suffering from typhoid fever, the germs grow and constantly produce the ptomaine which is absorbed and causes the symptoms of the disease. If our extract contains the typhoid fever poison, we should expect it to produce, when employed as in the above experiments, in general the symptoms of the disease, but we should expect these symptoms to be temporary. We think that this is substantially what is shown by the experiments. The primary depression of temperature observed when the larger amounts were employed, is certainly nothing more than might be expected from a large dose of a powerful poison; then the elevation of temperature which followed was in the majority of the experiments at least sufficiently marked. We did not expect to find in the animal examined the characteristic intestinal lesions of typhoid fever, as we suppose these to be due to the growth and activity of the microörganism, or to the local action of the ptomaine where it exists in largest amount—the place of its formation.

In 1885, Brieger,[1] of Berlin, obtained from pure cultures of the Eberth bacillus, a ptomaine which in guinea-pigs produced a slight flow of saliva, frequency of respiration, dilatation of the pupils, profuse diarrhœa, paralysis, and death within from twenty-four to forty-eight hours. Post-mortem examination showed the heart in systole, the lungs hyperæmic, and the intestines contracted and pale. This substance Brieger considers the special poison of typhoid fever, and calls it typhotoxine, and it may be that we shall find that it forms the active principle of our syrupy residue. At present, however, the two do not seem to be identical. Brieger found no elevation of temperature, at least he does not refer to it, while property of elevating the temperature seems to be the most characteristic effect of the Iron Mountain water poison. Typhotoxine produced profuse diarrhœa; while the other poison has shown no such effect. It may be remarked here that the fever at Iron Mountain has been characterized by the existence of constipation in the majority of cases.

However, these differences in physiological action may be due to the fact that different animals were used, guinea-pigs in one case, and cats in the other.

In 1880, Eberth[2] first described an oval bacillus, which he had found in the spleen and mesenteric glands of persons dead of typhoid fever, and which is now generally believed to be the true germ of this disease. Before Eberth, Koch had observed this germ and had taken micro-photographs of it. Even before Koch, Browicz,[1] Sokoloff,[2] Fischel,[3] and others had individually observed in the tissues of typhoid subjects, oval bacilli, which were probably identical with those of Eberth and Koch.

These bacilli are about one-third as large as the red blood-corpuscles of man, and about three times as long as broad; though they may grow to long threads. The short rods have plainly rounded ends, and very active movements. They are affected by the aniline colors less than most germs, and are best stained by methylin-blue. Whether or not this germ produces spores is a question of much interest to bacteriologists. Gaffky[4] found that in potato, gelatine and blood serum cultures, kept at the temperature of the body, spores were formed. This observation has been confirmed by Sternberg,[5] Flügge and Bolton,[6] Vilchour,[7] and Chantemesse and Vidal;[8] though on the other hand, Buchner,[9] Seitz,[10] Michael,[11] and Fränkel and Simmonds[12] have, after numerous investigations, been unable to detect any spore formation. This question is also of interest to sanitarians, since germ-spores resist disinfectants, which destroy germs growing without spores. Very recently Birch-Hirschfeld[13] has apparently settled this question by detecting the spores by growing the bacillus in stained cultures. Another point of interest to sanitarians is the capability of this germ to resist high and low temperatures. Prudden[14] found them capable of growth after having been frozen in ice for 103 days and after having been heated to 132.8° F. This confirms the belief of sanitarians in this country that typhoid fever may be induced by the use of impure ice. The same investigations showed that frequent, alternate freezing and thawing did destroy the germ.

Still another point of interest is the fact that this germ will grow in various media. Seitz,[15] and Wolfhügel and Riedel[16] found that it grew abundantly in milk. In our experiments, as has been seen, we obtained the poisonous extract from both the milk and meat cultures, though it was more abundant in the latter. It is worthy of note that the milk culture became acid in reaction, a fact which has also been observed by Löffler.[17] Seitz found that while the bacillus grew in both acid and alkaline urine, its

growth was more abundant in the latter. However, it is probably of no sanitary importance whether the germ be taken into the stomach in milk or in water, for, in either case, on reaching the small intestine, it will find an alkaline medium in which to multiply. Wolfhügel and Riedel found that the bacillus multiplied in water which had been boiled, when kept at 60.8° F. Bolton found the "spores" in stagnant water a month and longer after the introduction of the germ. Hochstetter[1] found the germ in artificial seltzer water a week after its introduction. Seitz found that quinine, kairin, antipyrin, thallin, salicylic acid, and calomel in certain proportions arrest the growth of the germ in cultures, but that naphthalin, which seems to be a useful intestinal disinfectant in some diseases, is without effect upon the typhoid bacillus.

Upon potato, the typhoid bacillus shows a characteristic growth. It forms a mould wholly invisible to the unaided eye. After three or four days, if kept at ordinary temperature, after two days if kept at the temperature of the body, the surface of the potato looks moist, but no other change is observable. If the surface be scraped with a sterilized needle, and the material thus obtained be examined under a sufficient power, it will be found to consist of active, moving typhoid bacilli. By making potato cultures, this bacillus can be distinguished from all known germs. Indeed, the best bacteriologists regard the potato culture as the crucial test for the typhoid bacillus, and this test must always be made before one can be certain that he has this germ.

That the Iron Mountain water contained the typhoid bacillus was demonstrated by the potato culture and by microscopical examination, as well as by a physiological experiment. The first cultures were made as has been stated, November 9th, about two weeks after the water had been received. These cultures contained, besides the typhoid bacillus, germs ordinarily found in water; but the second cultures, made December 7th, contained only the typhoid bacillus. These had either destroyed or outlived the non-pathogenic organisms. This is an interesting fact, since it shows the poisonous germ to be very tenacious of life. Moreover, this observation is at variance with that of Kraus,[2] who found that the ordinary water bacteria destroyed the typhoid bacillus, though this difference may be due to the different temperatures at which the water was kept. Kraus kept the water in his experiment at 51° F., while the Iron Mountain water was kept in a jug, in a basement room, the temperature of which was about 68° F.

In meat peptone preparations the bacillus formed a scum, which had the lustre of mother-of-pearl, and was bluish-gray, becoming slightly brownish after some weeks. Some of this growth was removed with a sterilized rod, rubbed with two c. c. of water, which, when boiled, was taken into a large, sterilized hypodermatic syringe and injected into the abdominal cavity of a cat. Before the injection the hair was cut from the abdomen at the place of injection, and the skin was washed first with absolute alcohol, and then with one-half per cent. solution of mercuric chloride.

The injection was made at 2:25 P. M., December 20th. The temperature of the cat, taken in the rectum, before the injection, was 101.5°. Twenty minutes after the injection, there was a fecal movement, and a few moments later, the animal vomited. The vomiting was repeated four or five times during the afternoon. When not vomiting or attempting to do so, the animal seemed greatly prostrated. She rested on her abdomen with her chin upon the floor and could not be easily aroused. She made several attempts at stool, but there was no purging or diarrhœa.

Dec. 21, 7 : 45 A. M. The cat still lies in the same position. She refuses food. The temperature in the rectum is 96.4°.

2 : 30 P. M. Cat still lies upon the floor and refuses milk. Temperature 98.5°.

4 : 20 P. M. Temperature 101.4°.

5 : 30 P. M. Temperature 101.8°.

22d, 8 A. M. Cat seems better, but refuses food, and is very weak. She is unable to cry aloud; temperature 103°.

2 : 30 P. M. Takes some milk; temperature 104°.

4 : 20 P. M. Temperature 104.4°.

23d. The cat seems to be recovering rapidly. She takes food greedily, and the temperature is normal.

The animal was then killed with chloroform. There was nothing abnormal at the point of injection. Nothing abnormal could be found in the peritoneal cavity. No trace of the small masses of injected bacilli could be found. The mucous membrane of the small intestine was slightly hyperæmic and in the region of Peyer's glands were observed four little ulcerations about the size of a pin head. Two or three similar ones were found in the ascending colon, but one of these was about four times as large as those in the small intestine, and around this was quite an area marked by inflammatory action. Careful inspection of all the abdominal and thoracic organs failed to reveal any further abnormality.

This result was very satisfactory, and leaves no room for doubt concerning the existence of the specific poison of typhoid fever in the Iron Mountain water.

It is to be noted that the lower animals are not subject to long-continued typhoid fever as is man, and a temporary effect from which the animal would within a few days die or recover is all that can be expected. Besides, the lesions in our experiment were certainly satisfactory. We hope to repeat this experiment several times.

[1] Centralblatt für Bakteriologie und Parasitenkunde, B. I.

[2] Archiv für Hygiene, B. 6.

It will be interesting to know something about the sanitary condition of Iron Mountain. For our information upon this point we are wholly indebted to Drs. J. A. Crowell and G. B. Johnson, physicians to the Chapin mine, who have been kind enough to answer our numerous inquiries.

Iron Mountain is a village with a permanent population of about 4800, and during the summer months this number is augmented by some 2000 floating population. As there are only about 1000 buildings all told, and as some of the dwellings are very small, the village is very much crowded. The village is situated in a valley, the lowest portion of which was once a swamp, extending north and south. Upon each side the hills are steep, and portions of the village lie upon these hillsides. The soil is drift of sand and gravel, except in the lowest portions of the valley, where the drift is overlaid with vegetable mould. The depth of the drift is very variable. In some places, the ledge of rock, which is of the Huronian strata, outcrops on the hilltops; in others, on the hillsides; and in others, in the valley. The ledge stands nearly on edge, dipping at from 70 degrees to 80 degrees to the north. The drift is so porous that within twenty-four hours after heavy rains, the surface becomes dry.

A portion of the village, about three hundred houses, has a system of water-supply, the source of which is a shaft forty feet deep, and far away from any source of contamination. An analysis of this water by Messrs. Brewster and Brown, chemists to the Chapin mine, shows the following:

Free ammonia, parts per million	0.02
Albuminoid ammonia, parts per million	0 05
Chlorine, grains per gallon	0.4
Calcium carbonate, grains per gallon	10 476
Magnesium carbonate, grains per gallon	5.324

Dr. Crowell writes: "Those drinking this water have been almost wholly exempt from the fever, and yet there have been some remarkable exceptions, a whole family coming down, while all the neighbors were free from sickness, and all drinking of this water."

The remaining portion of the village, the part in which the fever prevailed, derives its drinking water from wells sunk from six to twenty feet. There are no sewers or other means of removing filth. Privy wells are used, and slops and garbage are thrown out in backyards and streets. During the past summer, a most disagreeable odor of decomposing matter greeted one in passing along the street. There is a ditch running through the village, which conveys the water from the mine to a small lake beyond the village. This ditch, quite naturally, is used by many as an open sewer, and the ice supplied the village last summer was taken from this small lake into which the ditch empties.

Dr. Johnson writes that the outbreak of typhoid fever appeared early in August, following a severe epidemic of dysentery. Up to December 21st, he knew of three hundred and fifty cases, about ten per cent. of which had terminated fatally. The later cases, however, are much more malignant than those which occurred during the summer and early fall. Persons have presented themselves daily at the office for a week, complaining of pain in head, chest, and back, loss of appetite, and distressing feeling of langour, but have shown no elevation of temperature, then, within twenty four hours, the temperature will be up to 104° or 105°. Diarrhœa was not present in the majority of the cases; indeed, constipation was more frequently the source of trouble.

The well (known as the Davis well) from which the water was taken which was sent to us, is sixteen feet deep. It is situated under the house, and is forty feet from the stables and privy. Thirteen of the inmates of the house had the fever. (The doctors have failed to inform us of the total number occupying the house or using the water.)

An analysis of the water by Messrs. Brewster and Brown shows the following:

Free ammonia, parts per million	2.27
Albuminoid ammonia, parts per million	0.26
Chlorine, grains per gallon	8.00

These figures give unquestionable proof that the water is contaminated with animal excretions.

Manning's well, situated just across the street from the Davis well, is a driven well, carried down into the rock, and furnishes a fairly good water, notwithstanding the fact that surroundings are bad. Brewster and Brown give the following result of their analysis of this water:

Free ammonia, parts per million	0.017
Albuminoid ammonia, parts per million	0.070
Chlorine, grains per gallon	0.050

Dr. Crowell informs us that it has been decided to supply the village with water from some springs, the analysis of which shows the following figures:

Free ammonia, parts per million	0.032
Albuminoid ammonia, parts per million	0.039
Chlorine, grains per gallon	0.10
Calcium carbonate, grains per gallon	5.090
Magnesium carbonate, grains per gallon	3.558

There can be no question about the need of a supply of pure water. This should be obtained by all means, and some provision should be made for disposing of excrement, slops, and garbage. It matters not how cold it may be this winter, the low temperature will not destroy the typhoid germ unless there be successions of freezing and thawing. And with the soil filled with these germs, some of them will be likely to find their way into the air breathed, food eaten, or water drank, and produce the disease. It should also be remembered that typhoid fever may be caused by the use of impure ice.

Since writing the above, Dr. Crowell has furnished us with some additional facts of interest. "The fever was brought to the village by a man from a

railroad construction camp. This man died a few days after his arrival. The symptoms were very variable. In some they were typical from beginning to end, but in others they were very irregular. Constipation for the first ten days, and frequently throughout the whole course of the disease existed in half the cases; and the abdominal symptoms, pain, tenderness, tympanites, gurgling in the right iliac fossa, although certainly present in many cases, were conspicuously absent in a very large number. Intestinal hemorrhage occurred quite frequently, and was the cause of death in one case in which we could never find any elevation of temperature. A subnormal temperature was very frequently observed, not only in the start, but throughout the disease. Failure of heart power, perforation, hemorrhage, pneumonia, and meningitis, in the order named, were the causes of death. In only one case could we get an autopsy. It was one in which the symptoms were least like typhoid. The temperature was low, and there were no abdominal symptoms, and no diarrhœa; yet the ileum was darkly congested, there were ulcerations of Peyer's patches, and although no perforation could be seen, when the gut was inflated, it slowly collapsed."

In conclusion, we may state that there cannot be any doubt that the epidemic at Iron Mountain is one of genuine typhoid fever. The intestinal lesions were observed in one post-mortem. Similar lesions were found in the cat, the specific germ of typhoid fever exists in the water, and the chemical poison, or ptomaine, is formed by the growth of this germ.

It is well known that typhoid fever invariably follows dry seasons, and is coincident with low water in wells (see paper by the Secretary of the Michigan State Board of Health, Report for 1884, pp. 89–114). There are, on an average, about one thousand deaths and ten thousand cases of sickness from this disease annually in Michigan. These figures can be greatly reduced if people will cease polluting the soil about their houses with slops, garbage, cesspools, and privy vaults, and will see to it that their drinking water is pure beyond all question. When there is any doubt the water should be boiled, but it should be remembered that, while the typhoid germ most frequently finds its way into the body with the drinking water, it may be taken in with any food, and even with the air. When a case of typhoid fever occurs, all discharges must be thoroughly disinfected, and the earth, water, and air about our homes must be pure if we escape this disease altogether.

OMPHALITIS.

BY CHARLES E. FAIRMAN, A.M., M.D.,
OF LYNDONVILLE, NEW YORK.

OMPHALITIS, or inflammation of the umbilicus, is an affection which may be easily overlooked. Pain, soreness, or distress in the region of the umbilicus, associated with intestinal obstruction, or various abdominal disorders, among which may be mentioned the initial colic of a typhlitis or general peritonitis, will, no doubt, be referred to proper sources. Most of the cases of omphalitis belong to the class of minor ailments, and in the vast majority of such cases a physician is not consulted. If inspection of the umbilicus is not practised in cases of pain, soreness, or distress in this region, omphalitis, when it exists, will not be detected. The affection may occur at any time of life. I give below the history of two cases lately observed.

CASE I.—June, 1887. A physician, æt. fifty-five, with cirrhosis of the liver and ascites, complained of pain at the umbilicus, which he referred to dragging by the liver. At his request I examined the umbilicus, and at first glance detected a dark ring around the umbilicus about one inch from the centre, and one-half inch in diameter. The navel was then closely scrutinized, and moisture and excessive redness appeared. At the bottom of the umbilicus there were five or six spots of minute ulceration and a few drops of pus. The umbilicus was carefully probed, but no fistula existed. Ordered injections of zinc sulphate (gr. iv to aq. ℥j), after which the umbilicus was to be carefully dried by absorbent cotton, then sprinkled with powdered iodoform to be retained by packing the navel with absorbent cotton. The symptoms quickly disappeared.

CASE II.—Mrs. W., in August, 1887, brought her son, æt. five, to my office. complaining of pain and distress in the umbilical region. I questioned the lady closely about gastro-intestinal symptoms, but got no history of such. The child's bowels moved regularly and painlessly, and appetite, digestion, and general appearance were normal. Puzzled to explain the symptoms, I inspected the navel, and found omphalitis, due to a neglect of toilet. I ordered thorough ablutions and antiseptic applications. Case did not return.

Causes of Omphalitis.—The causes of omphalitis neonatorum, or inflammation of the navel in infants, may be found described in text-books on obstetrics or diseases of children. Traction upon the cord, retarded birth, friction, and the access of germs have been assumed to bear a causal relation to this form of omphalitis. The causes of omphalitis proper, may be enumerated as follows:

(1) Want of cleanliness in the umbilical toilet.

(2) Injuries, blows, wounds, etc. From irritation of rough edges of starched shirts, etc.

(3) From vesication or counter-irritation applied to the surface of the abdomen.

(4) From umbilical fistulæ and herniæ; from abscess discharging at the umbilicus; from umbilical malformations,[1] and from furuncles in the umbilical region.

[1] Holmes's Syst. Surg., Amer. ed., vol. iii. p. 853.

Periomphalitis, or inflammation of the tissues surrounding the umbilicus, may also be caused by the above agencies. Thus, in Whitman's case (loc. cit.), is said, "On examination, it was seen that inflammation and ulceration extended to some distance around the umbilicus."

Symptoms.—Soreness, distress, and pain, at the umbilicus. Patients will sometimes try to relieve their distress by rubbing the umbilicus, or by placing the tip of the finger over the umbilicus, and rotating the finger. Periomphalic redness may be present if the inflammation is severe. Redness of the umbilicus in the milder cases may be seen by putting the umbilicus upon the stretch so as to obliterate the folds, and permit deep inspection. Some amount of swelling supervenes. In simple uncomplicated inflammation of the umbilicus, not occurring as a sequel of hernia, abscess, fistula, or fungus umbilici, I have never seen pouting or protrusion.

An offensive odor sometimes reveals the trouble, as was the result in Whitman's case (loc. cit.). Periomphalic ulceration is at times present. Pus and deep omphalic ulcers may be seen, as in Case I. In some cases a ring of black color encircles the navel. This ring is formed from umbilical discharges and extraneous matter.

Diagnosis.—When patients complain of soreness, distress, or pain at the navel, when nurses or mothers speak of foul odors or discharges therefrom, an ocular inspection of the umbilicus should always be made. The whole depth of the umbilicus should be examined (if necessary with a lens and concentrated light). Simple omphalitis will be easily made out.

The smeared circle around the umbilicus may point to the trouble even if no redness on simple inspection be apparent. Pouting and redness may point to abscess, fistula, hernia, polypus, or fungus umbilici. Therefore, omphalitis must not be confounded with umbilical hernial protrusions, nor with biliary fistulæ opening at the umbilicus.[1] In Slocum's case there were pouting and soreness in the umbilical region followed by an opening at the umbilicus and the discharge of bilious fluid, a little pus, and eleven calculi ranging from 5/8 to 1 1/8 inches in circumference, of a brownish-yellow color and mostly with six facets.

Fecal[2] and urachal fistulæ[3] must be excluded. Furuncles can be readily diagnosed. Herpes, of which I have seen a form which seemed worthy of the specific appellation of herpes umbilicaris, must not be taken for omphalic ulceration. Epithelioma[4] of the umbilicus I have never seen, but presume it could be readily excluded.

In the case of fungus umbilici of Gatchkoosky[4] there was a "bright red, solid, globular, umbilical tumor" in a child of two months (case recovered under use of powdered resorcin). The fleshy polypi[1] must be taken into consideration. According to Morris,[1] fleshy umbilical polypi are more or less pedunculated, red, moist, and sometimes associated with fistulæ which admit the probe to a long distance. In Dr. C. W. Stickney's case of abscess,[2] which was due to "either abscess of the abdominal wall external to the peritoneum or localized suppurative peritonitis circumscribed by adhesions," the umbilicus *protruded* as a rounded red tumor which soon fluctuated and ruptured, discharging a small quantity of healthy pus.

It may be well here to allude to the diagnostic significance of periomphalic color and hardness. I have already called attention to the black ring around the umbilicus in Case I. Dr. S. B. Bond believed that a red ring encircling the umbilicus in a newly born child pointed to retarded birth.[3] In one of his cases the ring was *bright red and less than two lines wide.*

Prophylaxis.—In the prevention of umbilical inflammation according to Drs. Credé and Weber[4] the desideratum is a dressing which shall allow the process of desiccation and separation to go on undisturbed. They wrap the stump of the cord in absorbent cotton, and leave it loose under the "belly band." The following methods may also be tried: dressings of salicylic starch powder and various antiseptic occlusive applications. In a word, measures which prevent traction, friction, and sepsis.

In older patients proper washing of the umbilicus should be enjoined. The hygiene of the umbilicus is not often referred to, and its toilet imperfectly performed, thereby allowing offensive secretions, epithelial scales (scurf), and fragments of organic matter—*i. e.*, dirt, fibres of cotton and wool—to accumulate within the umbilical recesses, thus forming a veritable culture cup in which I should not be surprised to learn that some bacteriologist had found special bacteria, as Rosenbach's[5] bacillus saprogenes No. 1 may (as Hauser[6] so graphically says) be obtained "aus stinkendem Fusschweiss."

Furthermore, the following rule may be laid down: do not blister the umbilicus if you do not want a troublesome case of omphalitis.

Treatment.—The treatment of omphalitis should be antiseptic. The navel must be thoroughly cleansed by washing, or injections of carbolized or sublimated solutions. The navel is then to be dried

and dusted with iodoform (resorcin, etc.), and then packed with simple, or borated, or iodoformed absorbent cotton. If necessary, a few strips of plaster will retain these dressings. In cases attended with indolent ulceration (endomphalic) I have recommended injections of zinc sulphate.

In omphalitis resulting from abscess, fistula, fungus umbilici, hernia, polypus, or sarcoma, treatment would be merged into that for the more serious trouble.

MEDICAL PROGRESS.

The Treatment of Habitual Constipation by Enemata of Glycerine.—Dr. Althaus has found the following plan of treatment of value:

At a time when not only the tedious proceeding of massage, but actually manipulation of the abdomen by cannon balls is recommended for chronic constipation, a far simpler and more effectual way of inducing peristaltic action of the bowels, which has recently been discovered, should be brought to the knowledge of the profession generally. This consists of the injection into the rectum, by means of an ordinary glass syringe, of about half a teaspoonful or a teaspoonful of glycerine.

An evacuation generally takes place, either immediately or within a few minutes after the injection. The explanation of the effect given by Anacker, and which is no doubt the true one, is this: Glycerine when brought into contact with the mucous membrane of the rectum, withdraws water from it, thus causing hyperæmia and irritation of the sentient nerves of the rectum, which in its turn leads reflexly to powerful peristaltic contractions, ending in defecation. The larger the accumulation of feces, the greater is the effect. There is no discomfort or pain, but the action takes place *cito, tute et jucunde*. Sometimes, however, a little throbbing is felt in the rectum for a few minutes afterward. I feel sure that this plan, on account of its simplicity and readiness, will be found to constitute a veritable improvement in the therapeutics of constipation.—*British Medical Journal*, Dec. 24, 1887.

Amylenhydrate in the Treatment of the Insane.—Lehmann reports 149 observations on the action of amylenhydrate, on 26 insane women, in an asylum. The doses varied from 15 to 75 grains; on one occasion 90 grains were given. It was given shaken up with water. In 83.2 per cent. of administrations good effects resulted. In the cases of 11 maniacal women the remedy was effectual, in large doses. In melancholia the results were less marked. In two cases of chronic mania, with hallucinations, good results were obtained. In the paralysis of the insane it was also useful. The effect of the remedy was produced in from five to fifteen minutes after administration, and was purely hypnotic. The sleep resulting lasted from six to eight hours. The only unpleasant after-effects noticed were feeble nausea and gastric uneasiness on the day after taking the drug. Amylenhydrate is more efficient than paraldehyde, and although its odor is not agreeable, it does not cause offensive eructations, as does paraldehyde.—*Therapeutische Monatshefte*, December, 1887.

Antipyrin in Epilepsy.—Lemoine, in an article in the *Gazette Médicale de Paris* of December 24, 1887, concludes that antipyrin is inert in the majority of epileptics; those cases which may be benefited by it are—

(1) Those in which epileptic paroxysms are induced by menstruation.

(2) Those patients whose paroxysms are induced by the irritation of intestinal parasites.

(3) Epileptics whose attacks are attended by migraine.

Antipyrin, in quantities of thirty grains per diem, is superior to bromide of potassium in the cases specified.

Antifebrin in Phthisis.—In the *Wiadomosci Lekarskie*, Nos. 5 and 7, 1887, Dr. Stachiewicz published an able paper on the treatment of phthisis by antifebrin. The paper is based on twelve cases admitted to Dr. Brehmer's hospital in Goebersdorf for pulmonary diseases. They were arranged in three categories, one of which included emaciated and weak patients, with an old standing and still progressing disintegration of the pulmonary tissues; another, those with recent progressive disintegration, the general state being still fairly good; and a third, those with old cavities and slowly progressing infiltration of adjacent parts of the lung, but still in fair general health. Analyzing the cases, Dr. Stachiewicz arrives at the following conclusions: In patients belonging to the first group, antifebrin should be administered in small doses, such as two grains to one grain Given in doses of four grains it produces in weak persons profuse perspiration and often rigors. The lowering of the febrile temperature takes place in an hour after the administration, reaches its maximum in three or four hours, and lasts from six to eight hours. In patients of the second group, the dose should amount to from four to seven and one-half grains. The antipyretic action develops itself in one or two hours after administration, lasts from three to five hours, and is not associated with rigors or vomiting; sweats and cyanosis are seldom met with; the amount of urine remains unchanged; the pulse becomes slower and fuller. The same may be said as regards patients of the third group. In them antifebrin should be given in doses of four to seven and one-half grains as soon as the temperature rises to 99.8° F.; if a reëlevation of the temperature occurs later on, another dose should be administered. On the whole, the author places antifebrin far above all other antipyretic remedies. —*British Medical Journal*, December 24, 1887.

Omeire.—The German colonist in Southwestern Africa have observed the use of a drink among the natives, composed of fermented milk. In corresponds to kouniss and kefir, and is produced by the action of a ferment similar to that of these beverages.

Marloth reports that omeire contains alcohol in small quantities, and that after six or ten hours' fermentation the casein separates from the milk completely.—*Therapeutische Monatshefte*, December, 1887.

The Treatment of Constipation in Children.—From a review of various methods of treatment, by Huchard, in the *Revue Gén. de Clin. et Thèr.* of December 29, 1887, we take the following prescriptions:

For infants Widerhofer uses

Mannit.	grs. 6.
Aquæ bullient.	ʒ 10.

Mix, and allow to cool. A teaspoonful for a newborn child.

Castor oil may be made less objectionable to children by combining

Castor oil,
Malaga wine . . . āā ♏ 75 to ʒ 2½.

Widerhofer combines rhubarb and magnesia as follows:

Rad. rhei pulv.,
Magnes. calcin.,
Fœniculi. Equal parts.

As much as will lie upon the point of a medium-sized knife blade may be given to an infant in the morning, and repeated, if necessary.

In the more obstinate constipation of older children, Simon has found the following liquid efficacious:

Tinct. cascarillæ,
Tinct. rhubarb.
Tinct. cinnamon.
Tinct. colombo,
Tinct. gentian. . . . . āā ʒ 2½.
Tinct. nucis vom. . . . . ♏ 75.

For children older than three years, 10 drops of this mixture may be given in cold water before meals.

Widerhofer prescribes pepsin as follows:

Pepsin . . . . . grs. 9.
Sacchar. lac. . . . . grs. 60.

In four doses: two doses daily, before nursing.

After nursing,

Acid. hydrochlor. . . . . gtt. 5.
Aquæ destill. . . . . ʒ 10.

Two small teaspoonsful may be given twice daily, five minutes after nursing.

Henoch prescribes,

Pepsin . . . . . grs. 15.
Acid. hydrochlor. . . . . ♏ 7½.
Aquæ destill. . . . . ʒ 30.
Sacchar. . . . . ʒ 2½.

A teaspoonful four times daily.

Bouchut has used the following for infants:

Podophyllin. . . . . gr. ¾.
Syrup. althaeæ . . . . . ʒ 22.
Cognac . . . . . ʒ 3.

Dose, 1 or 2 teaspoonsful.

Cascara sagrada and saccharin may be combined as follows:

Ext. cascar. sagrad. (alcohol.) grs. 7½.
Glycerin. pur. . . . ʒ 12½.
Saccharin. . . . . grs. 3 to grs. 7½.

Dose, 1 or 2 teaspoonsful; if the bitter taste of the cascara is not disguised by the saccharin, tincture of cinnamon will be found useful.

West considered licorice as especially adapted to children, and prescribed it as follows:

Glycyrrhizæ . . . . . ʒ 15.
Sennæ . . . . . ʒ 15.
Sulphur. lot. . . . . ʒ 7½.
Fœniculi . . . . . ʒ 7½
Sacchar. . . . . ʒ 45.

Dose, proportionate to age and peculiarities of the case.

Tetanus Cured by Morphia and Cocaine.—LOPEZ is quoted by the *Journal of Nervous and Mental Diseases* for December, 1887, as reporting in an Italian journal the following case:

M. G., fifty years old, having worked in the cold and wet, complained of rheumatic pains in the back and extremities. Three days after he had an attack of opisthotonus and painful spasms, and all the symptoms of idiopathic tetanus. Morphine and chloral hydrate were prescribed. For three days the patient, under the influence of these medicines, had little pain, but there were increased muscular rigidity and spasms. At last he was unable to swallow, and death was believed imminent. Injections of morphine were without effect. Then the writer injected three syringefuls of a mixture of morphine and cocaine, five per cent. of each. The effect was immediate. After two hours he could move the extremities, open his mouth, and turn himself in his bed. The next day he continued to improve. There remained a slight trismus and a little rigidity of the neck. A quarter of a syringeful of the same solution was injected in each side of the neck. The day after, all the symptoms had disappeared, and in a few days the patient gained strength and was able to return to work.

Cornutin.—LANGAARD, in an article reviewing the active principles of ergot, describes cornutin as having been used in 46 cases in the Midwives Clinic at Stuttgart by Erhard. The results were, a distinct effect in 34.7 per cent. of the cases treated; a probable effect in 28.2 per cent.; a doubtful effect in 17.3 per cent.; and no result in 19.5 per cent. Six of the children were stillborn, and Langaard advises against the use of cornutin without special caution in this regard. The dose employed was one-fifteenth of a grain, in pill form.—*Therapeutische Monatshefte*, December, 1877.

The Preparation of Koumissed Peptones.—In addition to the description of these food stuffs, published in the THE MEDICAL NEWS of December 31, 1887, we quote, from the *British Medical Journal* of December 24, 1887, DR. ANDERSON'S method of preparation, as communicated by him, as follows:

To prepare milk previously to being converted into koumiss: Obtain sweet "old or skimmed" milk; steam it until a fairly tough pellicle forms upon the surface, when set aside for twelve hours; then take off the pellicle and any and every particle floating on the surface; add 25 per cent. of pure soft water, and to each quart of the mixture add 20 grains of sodium bicarbonate, and one ounce and a half of either pure clover honey or fine white sugar. Mix in the ferment, namely, either about a quarter of a pint of fairly new koumiss, or, in the absence of this, the honey ferment described. Bottle at once in champagne bottles and securely cork and wire them. Submit them to a uniform temperature of about 80° F. for from twelve to twenty-four hours. A drop or two of koumiss, exuding through the cork, shows that the process is complete. The bottles may be shaken and put away in a cool place. The koumiss has now a slightly acid taste, and is fit for immediate use, but it will keep good for an indefinite period, except that it daily becomes more acid.

To prepare milk previously to being pancreatized or peptonized: Obtain sweet "old or skimmed" milk, and

steam and treat it in all respects as for koumiss. Add no water. Having removed the pellicle and floating particles, add a sufficiency of pancreatine, and to each quart of the steamed milk twenty grains of sodium bicarbonate. Keep the milk at a temperature of about 130° or 140° F. for the space of two hours, stirring about once each fifteen minutes. At the expiration of two hours, raise the temperature quickly to the boiling point, and then set aside to cool. If it is intended to peptonize by adding pepsin and not pancreatine, the sodium bicarbonate must be omitted until after the completion of the process (two hours), and after boiling. If it be intended that both pepsin and pancreatine be employed, then after the completion of the action of pepsin, and after boiling, the milk must be neutralized by addition of a sufficiency of sodium bicarbonate before adding the pancreatine. Milk "alone" I never peptonize, but I always pancreatize it. Having completed one or both of these processes, and allowed the result to cool, the same process is gone through as with ordinary koumiss, with the exception that no water is added.

One correspondent questions whether 25 per cent. of the water of milk is driven off during the process of peptonization. Considering that the milk is maintained for two hours at a not less temperature than 130° F., and then is boiled, I do not think the matter difficult to understand.

The honey ferment will keep active, if occasionally fed with fresh honey, or a little sugar.

The Hypnotic Action of Antipyrin in the Insane.—MAIRET and COMBEMALE have obtained the followiug results in the use of antipyrin among the insane.

More than fifty cases were treated by this drug, and its use was continued for several consecutive weeks. In a dose of 60 grains, given in aromatic water at bedtime, the remedy proved useful. As much as 120 grains were given at one time with good results. The effect varied with the type of insanity under treatment. In simple mania the effect varied with the acuteness and intensity of the paroxysm; in the more chronic cases a good result was obtained. In senile dementia antipyrin was useless.

In alcoholic mania, with or without organic lesions, a success, generally positive, was obtained; sleep for several hours, sometimes for an entire night, was secured. In general paralysis from alcoholism antipyrin failed. In epileptiform mania antipyrin produced sleep of considerable duration. It produced an effect, however, generally less well marked than that produced by digitalis and chloral, as given by these writers. The dose of 60 grains never produced toxic effects, although continued for a month; nausea and vomiting occurred twice, but the drug was well borne when repeated. The larger doses were given but a few times, but without ill effects. —*Gazette Hebdomadaire*, December 23, 1887.

The Administration of Hypnone.—LAILLER has given hypnone conveniently, in doses ranging from 20 to 80 drops, combined with alcohol, aquæ laurocerasi, and syrup of orange.—*L'Union Médicale*, December 11, 1887.

A New Deodorant for Iodoform.—HELBING is quoted by the *American Pharmacist* of December, 1887, as having had his attention called to the value of the essential oil of evoida fraxinifolia as a deodorant. He had an opportunity of examining the fruit of this plant, and found that it yields an oil having a most agreeable and powerful odor, which is even able to overcome the smell of iodoform, either in crystalline shape or in solution. For practical purposes it is only necessary to add a little (two drops to the ounce) of the essential oil to the disinfectant in order to obtain a complete dèodoration of the latter, the chief objection which has been raised against the use of this valuable remedy thus being obviated.

Local Anæsthesia in the Extraction of Teeth.—DIAN is quoted by the *Therapeutische Monatshefte* for December, 1887, as having injected a mixture of seven and a half grains of cocaine in ten minims of a two per cent. carbolic acid solution, half upon each side of the tooth to be extracted, injected beneath the gum. In 86 cases anæsthesia was produced in five minutes' time. Some have claimed that carbolic acid alone will produce the same result.

An Arsenical Cocaine Paste for Dental Use.—KIRK has found the following useful, and as little painful as any application, in devitalizing tooth pulp.

Acid. arsen. pulv.	gr. 15.
Cocaine hydrochlor.	gr. 15.
Menthol (crystall.)	gr. 4.
Glycerine	q. s.

—*Dental Cosmos.*

Contagious Pneumonia in Swine.—CORNIL and CHANTEMESSE have determined, by the examination of animals dying from this disease, that the malady is one generally infectious, whose pulmonary symptoms are caused by its mode of introduction into the economy, which is by inspiration of contagious matter. The post-mortem appearances are those of fibrinous pneumonia, and the experimenters demonstrated a bacillus which causes the disease.—*Revue Scientifique*, December 21, 1887.

Poisoning with Hyoscin; Recovery.—DR. GITHENS reports, in the *Therapeutic Gazette* of December 15, 1887, the case of an insane patient who, while she was alone, drank all that remained in a bottle, not less than four-fifths of a grain of hyoscin hydrobromate (granting that the prescription had been properly filled). Profound sleep was the only effect of this enormous dose. A neighboring physician was called in; he used towel slappings and other forms of personal violence, and administered croton oil. He did not see the patient until the next day, when all effects of the hyoscin had passed away, so he could tell nothing of the state of the pupils or skin. The latter was bruised from the violence, and her mouth, tongue, pharynx, and stomach, were in a terrible state of inflammation from the local action of the croton oil. He did not know why it was administered.

Osmic Acid, Hypodermatically, in Intercostal Neuralgia.—SEELIGMÜLLER has treated intercostal neuralgia by hypodermatic injections of osmic acid, in solutions of from one to ten per cent. The injections were made deeply into the muscles along the spine, and produced sharp pain at first, followed by relief.

In treating neuralgias of nerves containing both sensory and motor fibres, as the sciatic, the writer would not advise the use of a solution stronger than one per cent.,

fearing paralysis from stronger solutions. His usual dose in intercostal neuralgias was half or the whole contents of an ordinary hypodermatic syringe.—*Therapeutische Monatshefte*, December, 1887.

Hypnotics in Cardiac Disease.—SANSOM, in an article on aortic disease in the *Lancet* of December 31, 1887, writes that when the heart is very irritable and palpitation is frequent, a wakeful night may mean much mischief. As a hypnotic, the action of which is attended with no ill consequence whatever, he has employed urethan in a single dose of twenty grains at bedtime; but this loses its good effect by frequent repetition. Paraldehyde, in thirty-minim doses in almond mixture, may be given as an alternative, the dose being repeated in half an hour if sleep fails to come. These failing, as they do when pain and distress are severe, then the hypodermatic injection of morphia and atropine is the best course, and a few nights of such treatment may suffice to tide over the peril of insomnia. That insomnia is a peril in an aortic case he is well assured, though he is equally assured that the physician must take pains that the morphia habit be not inculcated.

Iodol.—TROUSSEAU has found the following formulæ useful:

For an ointment,

Vaselin.	℥ 2½.
Iodol.	grs. 30 to 60.

In solution,

Iodol	3 parts.
Alcohol	35 parts.
Glycerine	62 parts.

In disease of the lachrymal duct, the following was found a useful injection:

Liquid vaseline	℥ 7½.
Iodol	grs. 45.

—*Revue Gén. de Clin. et Thér.*, December 29, 1887.

Cataract and Albuminuria.—In view of the opinion that cataract is apt to appear in patients suffering from chronic nephritis, DR. F. O. EVETZXY (*Vratch*, No. 7, 1887, p. 170) has examined the urine and the eyes in 200 cases of cataract at the Moscow Ophthalmic Hospital, in 87 cases of nephritis, and 561 aged persons (inmates of several almshouses). The following are his results: 1. Albuminuria has no influence whatever on the development of cataract. 2. No cataract was found in young patients suffering from nephritis; the affection was met with in old patients, but not more frequently than in elderly people with sound kidneys. 3. Both sexes are attacked by cataract with equal frequency. 4. The development of cataract is favored by bad nutrition. 5. Age has an enormous and essential influence on the formation of cataract. The number of cataract cases amongst the old is very large, the percentage increasing with the age.—*British Medical Journal*, Dec. 24, 1887.

Meat Broths for Children.—In the *Archives of Pediatrics* for January, 1888, JACOBI writes as follows on this subject:

Beef-broth is about as nutritious as whey, and no more. But on account of the extractive substances of beef, kreatin, and kreatinin, it is more stimulating. The temperature of the body is not raised by it. In gastric irritation, gastritis, and acute dysentery it ought not to be given. Veal-broth is liable to increase diarrhœa, mutton-broth constipation, and is therefore preferable in cases of diarrhœa. A broth of beef, which contains from 1.5 to 2 per cent. of albumen, is made by mixing one part of beef and six of water with a little chloride of sodium and allowing it to stand from ten to twelve hours. Then it is slowly boiled and the whole mass pressed out. Still better is a modification of Liebig's beef-tea, which is obtained by adding one half-pint of water, with six or seven drops of dilute muriatic acid, to a quarter or one-half of a pound of finely cut lean beef, stirring it occasionally during two hours, and boiling a few minutes. Beef-juice obtained by pressing out beef after slightly boiling it, contains from 6 to 7 per cent. of albumen. It is slightly acid and spoils quickly.

Excision of the Tongue for Epithelioma.—In the *Lancet* of December 31, 1887, BARWELL describes his method and its application in a recent case as follows:

The method is this. Strictly in and along the middle line an opening is made about one-third of an inch long immediately in front of the hyoid bone, through the raphé of the mylo-hyoid. The genio-hyoid and genio-hyoglossus muscles are separated with the handle of the scalpel until the deep surface of the mucous membrane forming the floor of the mouth is reached. By means of Liston's needles carried under this membrane to, or even beyond, the last molar teeth, threads are passed on each side into the buccal cavity, which in their turn draw flexible wire-twist, first into, then out of, the mouth, in such wise as to surround the base of the tongue as far back as one will. An écraseur working with this wire severs that part of the organ. Then the loop of another écraseur is passed between the teeth, pressed well down on the first incision, and divides the structures beneath the tongue.

In this way then, I operated on August 6th, on George G., aged forty-seven, who had a large epithelioma on the left side of the tongue, behind its middle; the induration, however, extended very far back and across to the other side of the organ. No enlarged glands could be felt. The ulcer was extremely sensitive: eating and even swallowing caused pain and trouble to him, while the very foul condition of the mouth took away all desire for food. During the operation but very few drops of blood were lost. Very soon after recovery from the anæsthetic he wrote on the slate that he was pretty comfortable. Aug. 8th: There had been a copious flow of saliva and other secretions from the supra-hyoid wound. The patient daily took a large quantity of milk and beef-tea, with, he says, more ease than he had done for a long time. The wound was frequently syringed and the mouth rinsed with a 1 in 60 solution of carbolic acid, and the breath was hardly at all tainted. 24th: On the 16th the man could comfortably eat finely minced meat, and had gained flesh since the last report. 30th: He left the hospital, the tongue wound being firmly cicatrized on the 27th. He was able to eat very well, and for the last ten days has been able to enunciate with considerable distinctness.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,

PHILADELPHIA.

SATURDAY, JANUARY 28, 1888.

SPLENECTOMY.

IN the *Archiv für klinische Chirurgie*, Bd. xxxvi., Heft. 2, ADELMANN, of Berlin, tabulates 53 cases of excision of the spleen for various affections. Omitting the cases of Ferrerius and Dorsey, which were not splenectomies, and adding 4 operations for floating spleen practised by Polk, Myers, Younker, and McCann, and 1 for leukæmia in the hands of Strong, we have 56 cases, of which 38, or 67.87 per cent., proved fatal, thereby showing a higher rate of mortality than laparotomy for any other cause.

The spleen has been removed for leukæmia 20 times, the only recovery having been recorded by Franzolini, in which the disease was in its incipiency. Of the 19 deaths, 14 were due to hemorrhage, 3 to shock, and 1 each to septicæmia and exhaustion. In 5 of the deaths from loss of blood the fatal issue ensued either during or soon after the operation; in 4 within twelve hours; in 3 within twenty-four hours; in 1 at the end of twenty-four hours; and in 1 in thirty-six hours. In the majority of the cases the bleeding occurred in separating adhesions and from rents of the organ. In one example it arose from slipping of a ligature.

Splenectomy for so-called simple hypertrophy, or chronic enlargement, shows 13 deaths in 14 cases, 1 from cirrhosis of the liver, 1 from septicæmia, 1 from peritonitis, 2 from shock, and 8 from hemorrhage, the rate of deaths from the last cause being 61.53 per cent., as against 73.68 per cent. for leukæmic spleen. One of these patients died on the table, and the remainder succumbed within twelve hours. In not less than one-half the vessel had been overlooked; in one the ligature had become detached; while in only one-fourth did the bleeding proceed from the surface of adhesions.

The three cases of excision for malarial hypertrophy were all fatal: 1 from septic peritonitis, 1 from shock, and 1 from parenchymatous nephritis. In two of these cases the loss of blood was profuse.

Wandering or floating spleens have been removed 13 times, with only 2 deaths, 1 from twisting of the stomach, and 1 from collapse. The operation has, moreover, been resorted to in 5 cases of cysts, of which 1 proved fatal, and in 1 case of sarcoma, which was successful.

It will thus be seen that splenectomy is indicated for floating spleen and cysts, and that it should positively be refrained from in all cases of hypertrophy, no matter from what cause that condition arise. The mortality for leukæmic enlargement is 95 per cent., for so-called simple hypertrophy 92.85 per cent., and for malarial hypertrophy 100 per cent. Hemorrhage was the cause of the fatal issue in 68.75 per cent. of the first two conditions; and as that complication was nearly as frequent in simple as in leukæmic enlargement, it is possible that leukæmia was present in a certain number of examples of the former condition. Even if absent, the so-called simple hypertrophy must so impair the hæmatogenetic functions of the spleen as to deprive the blood of its plasticity, and bring about a condition of hydræmia. Be this as it may, we take it that a simply enlarged spleen ought never to be excised. Should, however, excision be thought of, it must not be undertaken without a careful preliminary examination of the blood, and, if resorted to, great care must be exercised in hunting for and securing divided vessels, a point which had been neglected in one-half of the fatal cases from hemorrhage.

It may be added that, during the excision of a retroperitoneal sarcoma, Trendelenburg wounded and removed a healthy spleen, and that the patient died of hydræmia in three months.

THE ARMY HOSPITAL CORPS.

AMONG the older members of the profession in this country are many who once had a personal interest in army medical matters. A quarter of a century ago, our journals were filled with letters from valued correspondents at the front, articles on

hospital organization, camp sanitation, and camp diseases, and interesting cases from the experience of the great general hospitals. In turning over their pages, one may see how readily the profession buckled on the harness of war, and how interested were those who stayed at home in the fortunes and experiences of those who went away. At the present day, it is difficult to realize this old-time interest in the army, as we see the most important changes taking place in its hospital organization with scarcely a word of comment in the medical press. Yet many of those who served in the stirring times of the war would be interested in knowing that recently, and only recently, their own experiences have matured, and borne legislative fruit which will benefit the sick and wounded soldier in the future. Those who were in the field with their regiments will remember the fact that men detailed at their request for hospital duty were not those best qualified for it, but those whom commanding officers could spare with least detriment to the fighting strength of their commands; and the experience of those who served at general hospitals would, if recorded, be of a similar tenor, as a requisition for so many hospital attendants was usually filled by a detail of men who would have been sent to hospital as sick had they not been called for as nurses. The war demonstrated the necessity for a special body of trained hospital men; but year after year has passed, and not until even the police of some large cities have been educated and drilled in the methods of giving first aid in accidents has the Army of the United States been provided with a set of men qualified to perform such duties.

The Act of Congress, approved March 1, 1887, authorizes the enlistment of a special corps of men to be attached to the medical department, and to perform its duties under the orders and supervision of the officers of that department.

For post or peace service there is provided one hospital steward for every post—two, if the garrison contains six companies, and one additional for every additional six companies. There is also provided for every post of two companies, or of a single company of cavalry, an acting hospital steward, with privates at the rate of three for each post of one company, four for posts of two companies, with one man additional for each additional two companies. Each post-surgeon is provided with an ambulance and harness, which must be at all times in good order and ready for service, and with hand-litters, cacolets, travois, and mule-litters as may be required. Moreover, four men of each company are to be designated for instruction as litter-bearers. These bearers will be specially trained to enable them to render temporary aid to the sick and wounded of their organization; but their duties as bearers will not relieve them from their duties as soldiers. It is the intention that the corps of company-bearers shall form the training school for members of the hospital corps, and that the privates of the one will be recruited from the ranks of the other.

In the field in time of war the privates of the hospital corps will constitute two per cent. of the aggregate strength of the command, with an acting hospital steward to every ten privates, and a hospital steward to every thirty. They will perform the duties of litter-bearers, services with the ambulances, at the primary dressing and ambulance stations, and at the field hospitals of the command. They will be organized into a company for each brigade, with their hospital stewards and acting stewards as non-commissioned officers, under command of an officer of the ambulance service or a medical officer detailed for that purpose, and will habitually camp near the division hospital, or, if there be none, near the brigade or field hospital, to give such assistance as may be needed. Ambulances will be allowed and attached on a basis of one to a regiment of infantry of less than 200 men; two to a regiment of from 200 to 500 men; three to a regiment of more than 500; one or two to a regiment of cavalry, according as the latter has more or less than 500 men, and one to a battery of artillery. These, commanded by suitable detailed officers, will be under the control and supervision of the medical director. General hospitals are to have six privates to every thirty beds, with as many stewards and acting stewards as may be required. Hospital boats and cars will be similarly provided.

Outside of the special enlistment of the men for service under the orders of the medical department, the greatest gain to the department lies in the qualifications required for enlistment and promotion. No man may become a hospital steward without having demonstrated his fitness for the position by a year's service as an acting steward, and the latter position is only open to those men who have served a year as privates in the corps. This prevents unmerited promotion; but it has the disadvantage of excluding from the corps thoroughly qualified men who might otherwise be inclined to accept the posi-

tion of steward. A graduate of pharmacy or medicine may not, under the terms of the law, be appointed to a stewardship without passing through the preliminary terms of discipline and probation; few qualified pharmacists would be willing to do this. The uncommissioned officers of the corps must therefore be educated in its own ranks, and by its own officers. Every medical officer has to supervise the instruction of his men and the higher education of his stewards; the latter guide and direct the acting stewards, and these perform similar offices for those who serve under them. Promotion is awarded as the result of competitive examination: First, by a board of medical officers convened at the post at which the candidates are serving, and second, by written papers issued from the Surgeon-General's Office at Washington. The character of these papers call for a high grade of intelligence and knowledge on the part of the candidates. In addition to their knowledge of arithmetic, their familiarity with hospital reports and returns, the preparation and serving of food, and the use of the meteorological instruments, and hospital and field appliances furnished by the medical department, candidates for a stewardship are examined on pharmacy and materia medica as the professional basis of their fitness for dispensing, on minor surgery and the recognized modes of action in the face of medical and surgical emergencies as showing their fitness for field service, and on the elements of hygiene, particularly as related to the sanitation of camps and hospitals. The hospital steward has to be more than a mere dispenser of prescribed drugs; he must be prepared on occasions to take the place temporarily of the medical officer, not only as surgeon and physician, but as health or sanitary officer. The new position is on a higher plane than the old, and the law which institutes it gives an increased, although not a proportionate, remuneration.

The results of these examinations, so far, are said to be very gratifying, as showing the men at present holding these positions to be generally capable of the duties newly assigned them. Surgeon-General Moore has taken much interest in the development of the corps, in the assignment of individuals in accordance with their merits, and in defining and limiting the extent of the professional subjects which the men are required to know. Post-surgeons, also, have done much to prepare those serving under them for their places under the new law. We may anticipate, therefore, that in a short time our army will have what it has never had heretofore—a special corps of men fully trained for all the accidents of peace, and the emergencies of war.

The experiment in progress in the development of this corps will be watched by medical officers connected with our militia organizations. Some prominent State officers have already made inquiries concerning it. Our army is small, but its constant service on a peace footing in the east, and a war footing in our yet unsettled west, will enable it to crystallize that which is of practical value around the nucleus of the new corps, and give to our State militia a system, ready formed, for adoption.

STOMACH-COUGH.

THIS often troublesome and annoying condition has been thoroughly studied, both experimentally and clinically, by such observers as Nothnagel and Ebstein, and several men almost equally well known. That the cough is purely reflex is generally believed by practitioners, although the exact method of its production is still in doubt. Irritable conditions of the stomach, particularly of the peripheral sensory nerves in this organ, undoubtedly predispose to it, and, if the patient be hysterically inclined, the diagnosis is the more readily made.

In a case reported by BULL, in the *Deutsches Archiv f. klin. Med.*, of December 9, 1887, occurring in a servant girl of twenty-four years, symptoms manifested themselves showing disordered gastric function, but these were scarcely sufficient to excite suspicion. The cough had been present for a long period of time, and had persisted notwithstanding the use of cough medicines. There was no history to account for any disorder of the nervous system, and as no physical signs were present indicating respiratory disease of sufficient vigor to produce trouble, the patient was carefully dieted, and the alimentary canal treated as indications arose. The food allowed was chiefly milk and finely powdered meats given in small and frequently repeated quantities.

These cases are, of course, by no means uncommon, but we think that many of the coughs which are treated as respiratory in origin, and which do not yield to ordinary treatment, may be due to gastric trouble.

Certain it is that every practitioner sees cases constantly in which the physical signs are by no means of sufficient importance to produce severe cough, and it would seem probable that in these cases the

few bronchitic râles are rather the result of the cough than factors in its cause.

SMALL PARKS OR OPEN SPACES.

THAT is a short-sighted and mistaken policy which ignores the provision of small parks or open spaces for the adornment of the city and the recreation of its inhabitants. Such spaces interspersed throughout the populated districts, adorned with trees and shrubbery, and properly cared for, interrupt the monotony of solid blocks of compact buildings, beautify the city, and yield hygienic advantages of no small value. They afford places for healthful recreation for the children of the vicinity, who otherwise would be denied this privilege. They please the senses, and help to cultivate a fondness for the beautiful in nature.

By the exercise of intelligent foresight, plots of ground, judiciously selected, could be procured at moderate cost in advance of the extension of building operations, and reserved for the future uses of the public. On the other hand, by neglecting this precaution, the opportunity is lost, as the enormous expense of procuring suitable spaces for public pleasure-grounds in districts already populated is sure to defeat the undertaking. In extending the plans of our rapidly growing cities, past errors should be retrieved as far as possible by wisely designating numerous spaces to be reserved for the adornment of the city, and for the pleasure, recreation, and health of future generations.

WE are glad to learn that DR. W. W. KEEN'S case of brain tumor which was operated upon December 15, 1887, is doing well. Ten days after the extirpation he had a sharp rise of temperature to over 104°, with diarrhœa and marked bulging of the flap, paresis of the right leg, paralysis of the right arm and right lower face with aphasia. These severe pressure symptoms, coupled with the considerable blood clot formed in the wound in the few days after the operation, led to the fear of suppuration and the wound, which had nearly healed, was reopened to some extent, but no pus was found. A hernia cerebri has, of course, followed, but this is healing slowly under the antiseptic dressings, and seems to be doing no harm. The leg and face have entirely recovered, the aphasia has disappeared and the arm is regaining its function. As six weeks have passed since the operation, it is reasonable to conclude that the patient will make a happy recovery. His intelligence has not suffered at any time.

THE Medical Society of the State of New York will hold its eighty-second annual meeting at Albany, on the 7th, 8th, and 9th of February, under the presidency of Dr. Alfred L. Loomis. The programme is very full and attractive, and includes discussions on "Acute Bright's Disease," by Drs. Delafield, Jacobi, Roosa, Van Santvoord, Barker, Jewett, and Ely; on "Salpingitis," by Drs. Goodell, Mundé, Lee, Mann, Seymour, Castle, Polk, Wylie, and Vanderveer; on "Intestinal Obstruction," by Drs. Stimson, Wey, Vanderveer, Park, Weir, and Curtis; and on "Treatment of Tubercular Affections of Joints," by Drs. Phelps, Gibney, and Gerster. The President's Address will be delivered on the evening of the 8th.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 19, 1888.

THE PRESIDENT, A. JACOBI, M.D., IN THE CHAIR.

DR. H. CAILLÉ read a paper on

A METHOD OF PROPHYLAXIS IN DIPHTHERIA.

He said that in some households one or more members of the family, especially among the children, had an attack every spring or autumn, and it had occurred to him that in all probability in such cases the microbes of the disease remained permanently in the system, continuing in a dormant condition until some irritation or catarrhal inflammation of the faucial or nasal mucous membrane afforded an opportunity for the diphtheria to break out afresh. The disease was thus propagated by a process of auto-infection.

In order to make a practical test of the correctness of this hypothesis, he selected eight individuals of different ages, all of whom had had diphtheria at least twice, and some of them quite a number of times, prior to October 1, 1885. All belonged to families whom he had known for a long time, and who had continued to reside in the same house or apartments. The first thing that he did was to cause all carious teeth to be filled or extracted. He then directed the mouth to be thoroughly rinsed, and the throat to be gargled, and the nose to be cleansed, three times every day, with either a three per cent. solution of potassium permanganate, a weak solution of liquor sodæ chlorinatæ, or a saturated solution of boric acid; the different solutions being alternated with each other from time to time. In very young children the antiseptic solutions were dropped into the nostrils with a pipette. This practice was maintained throughout the year, except during the summer months, when none of the subjects had ever had diphtheria.

In addition to these eight cases, he ordered that from ten to fifteen drops of a saturated boric acid solution should be dropped into the nostrils of two infants, a year old, whenever any catarrhal symptoms manifested themselves.

The result of these precautions was, that up to the

present time, not one of the individuals referred to had had diphtheria since the system of prophylaxis had been commenced, although some of them during the time mentioned had been exposed to the disease by other members of the family having it.

While this result does not, of course, afford absolute proof of the prophylactic power of such a plan of procedure, it does go to show that if the nasal and oral cavities are kept clean by means of antiseptic solutions, diphtheria is less liable to occur than if no such precautions are resorted to.

It is a fact, that hitherto in diphtheria, far less attention has been paid to prevention than to the treatment of the disease after it has made its appearance. One reason why it is difficult to employ an intelligent prophylaxis, is because of our ignorance of the nature and significance of so-called diphtheria. Since we cannot in many instances distinguish between a contagious and a non-contagious sore throat, the problem presented is a very unsatisfactory one to handle. There is no specific treatment for diphtheria, and in the present state of our knowledge, prophylaxis is of more value to the public at large than treatment. Prophylactic measures can be divided into those relating to general sanitary conditions, and those confined within the family. It is an unfortunate fact that in a large city the great majority of the inhabitants cannot live in perfectly healthy habitations, and the great importance of individual prophylaxis is, therefore, obvious.

Dr. Caillé then passed in review a large number of works on practice and on diseases of children, showing that most authors scarcely allude at all to the subject of prophylaxis against diphtheria, while many others dismiss it with a few lines. Among those mentioned as devoting proper attention to it, were J. Lewis Smith and A. Jacobi. In speaking of the importance of keeping the upper air passages in good condition, with a view to preventing the occurrence of diphtheria, he quoted one writer as saying that a healthy throat has the same relation to diphtheria as a healthy stomach to cholera. In a city with densely populated districts, he went on to say, attention to the plumbing and ventilation of apartments, and sanitary conditions in general, must be supplemented by individual prophylaxis. The overheating of school-houses and dwellings is a constant source of danger, and isolation of those sick with diphtheria is not, as a rule, secured promptly enough. Enlarged tonsils increase the liability to diphtheria, and these should be removed with the knife, or, better, the galvanocautery. Carious teeth should be removed or filled, and he thought that provision should be made by which the poor could have dental cavities filled with cement or amalgam for nothing, or at a merely nominal price. He advised that parents should inspect their children's throats every morning before sending them to school, and that children should be taught how to gargle at an early age. Children with sore throats, however slight the trouble, should not be allowed to go to school, and kissing children on the lips should be forbidden. Parents should be urged to keep the upper air passages of their children in a healthy condition, especially if they are peculiarly susceptible to diphtheria. In young children, antiseptic solutions should be dropped into the nostrils twice a day, and oftener if there is any nasal catarrh present.

DR. GEORGE T. HARRISON said that he had had such painful experience in the treatment of diphtheria that he was especially glad to hear something in regard to the subject of its prophylaxis, and that he believed that the use of the precautionary measures advocated in the paper is a step in the right direction. He was also glad, he said, to hear Dr. Caillé emphasize the danger, as he had done in his paper, from so-called follicular amygdalitis, which the President of the Academy, Dr. Jacobi, had so strongly urged in his monograph on this subject in 1886. It is a matter in regard to which the profession, as well as the laity, needs to be on its guard.

DR. FRUITNIGHT said that it is a common experience to find that the first case of diphtheria in a family has advanced to a very dangerous degree before the medical attendant is called in, and, consequently, is very likely to prove fatal. It is also noticeable that afterward, in such families, the parents themselves often institute a system of prophylactic measures, making it a daily practice to examine the children's throats.

DR. S. BARUCH said that he should think that the daily washing out of the nose, by insufflation of antiseptic solutions or otherwise, is a very dangerous practice on account of the liability to excite serious ear-disease, especially if the fluid used is cold.

DR. T. R. POOLEY said that if the nasal douche were avoided, and warm fluids were used with an atomizer or by dropping into the nostrils he did not think there is much risk of causing disease of the middle ear. The safest and best method of washing out the nose is by means of the post-nasal syringe, which can be used with great facility after a little practice.

DR. CAILLÉ explained that he did not recommend the employment of cold liquids.

DR. SEIBERT said that he should like to add a word on the subject of prophylaxis, and that was in regard to the importance of keeping children's stomachs in good order, so that the mouth and tongue would be clean. In his experience a furred tongue is always a hotbed for the development of diphtheritic trouble, and he thought that the candy-shops in the vicinity of the public schools were responsible for a good deal of the diphtheria now so prevalent. These remarks, he said, were prompted to a considerable extent by his experience in the case of his own children.

THE PRESIDENT said that, if he understood the reader of the paper rightly, he believed that when a patient has once had diphtheria the germs of the disease are likely to remain secreted in the mucous membrane and lymphatic glands, and he quite agreed with Dr. Caillé in this opinion. Many of the cases of diphtheria of the greatest severity are those in which there is immense glandular swelling with œdema. Such cases are very likely to prove fatal, but if the patients recover the improvement dates from the time when these symptoms first begin to diminish. He felt sure, therefore, that diphtheritic germs are liable to remain in the lymphatics.

He desired to call attention also to another way in which the disease recurs. It had been remarked, that if the mouth is in a healthy condition, diphtheria is less likely to occur, while, if an epidemic of the disease appears in the locality where they reside, children who have a catarrh are especially liable to an attack. Diphtheria is like erysipelas in this respect. When there is an epidemic of the latter disease in a neighborhood the slightest scratch is likely to induce an attack of it,

while those who are free from any sore or abrasion of the surface escape. There is one point of great practical value in the prevention of diphtheria. It has often been noticed that cases in which it was thought that the patient was about over an attack of the disease had a relapse, and in some instances there were three or four attacks in quick succession. The reason of this was simply because the room, the bed, the curtains, the carpets, had become infected, and he had, therefore, made it a rule, whenever practicable, to change the room of the patient every two or three days, even if the room to which the removal was made was not as suitable for a sick-chamber as that first occupied. In some cases he had found it necessary to have the patient taken out of the house altogether.

Dr. L. Emmett Holt said he would like to ask, for information, whether there are any sufficient data to show that children with enlarged tonsils are more subject to diphtheria than others.

Dr. Caillé said that his own experience went to show that such children are more liable than others to be attacked, but he believed that, as a rule, in such cases the disease is of a comparatively mild form.

The President said that the reason why the tonsils are so frequently the primary seat of diphtheria is because they stand so much in the way of the air-current; so that deposits are likely to take place on them. Again, whenever the tonsils are enlarged there is a liability of mucus accumulating behind them. Enlarged tonsils are usually combined with a subacute or chronic nasal catarrh or pharyngitis, and the sooner, therefore, the tonsils are reduced and the pharyngitis removed, the better will be the prospect of the child's escaping diphtheria.

Dr. Joseph W. Winters said that when diphtheria appears in a family, in addition to enforcing strict isolation and attending to disinfection and the general sanitary condition of the premises, he inspects the throat of every member of the household daily, and, if there are children, orders them to take full doses of tincture of chloride of iron (say, twenty or more drops, three times a day), and tonic doses of quinine. At the same time he directs that they shall be kept in the open air as much as possible, shall sleep in rooms free from pipes connecting with sewers, and be given simple diet; while their digestive organs are maintained in good condition. To this end he usually orders small doses of mercury as a purgative, two or three times a week. When adopting these precautions he rarely saw two cases of diphtheria in the same family.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, January 11, 1888.

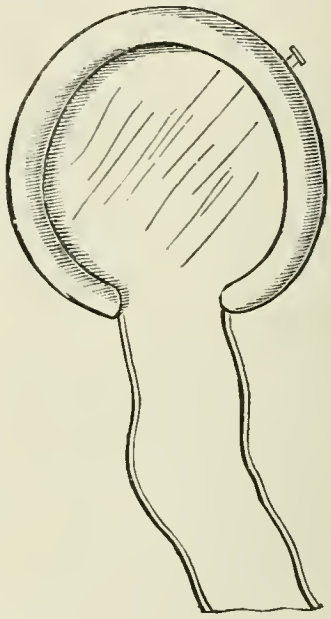
The President, J. Solis-Cohen, M.D., in the Chair.

Dr. Howard A. Kelly described his

RUBBER CUSHIONS FOR SURGICAL PURPOSES.

It is now almost a year, he said, since he put in the hands of Mr. Levick, manufacturer of rubber goods, several designs of cushions for surgical purposes. These cushions resemble those commonly used to sit on in having an inflatable rim, but differ in being left open on one side, being C-shaped or rectangular, with one side out. They have a bottom of rubber sheeting extended into an apron some inches in length for the purpose of drainage. He has had constructed three separate forms, a large C-shaped cushion measuring about twenty inches in diameter, the opening of the C being about eight inches across, and the apron twenty inches in length. The rim measures about two inches in diameter when inflated. This pad he constantly uses for abdominal sections, it is also of great service in obstetrical cases requiring operative manipulation. It permits the free use of water for douching purposes; drains all blood and water from the field, enabling the operator to return the patient at once to bed, without the necessity of removing clothing or changing linen.

A similar pad of the same pattern, measuring but ten inches in diameter, is in use on the examining table in his office, in all cases in which it is necessary to douch out the uterus or vagina.



The third pattern, which is in constant use for minor gynecological work, is the perineal cushion. It is rectangular in shape, opening on one side, having a rubber bottom and long apron similar to the preceding. When in use the patient's clothes are elevated, and the thighs held flexed on the abdomen by his "Beinhalter." The buttocks are drawn down over the edge of the inflated rim, and the apron which hangs down from the edge of the table carries off all blood and the water used throughout the operation.

There is no one device in all his gynecological work which has given him so much comfort as these simple cushions. He uses gallons of water with the utmost freedom, and without ever being obliged to think once where it is going. In perineal work, instead of using sponges, he uses constant irrigation, which prevents clotting of blood, soiling of instruments, and replaces at no expense, and with greater comfort and satisfaction, the sponges formerly used. The work thus accomplished is neater and cleaner, and the results are better.

He also presented a design for a rubber bed-pan. It is oblong in shape with an inflatable rim and a rubber bottom. It differs, however, from any previous device, in the fact that one end communicates with a large, funnel-shaped reservoir, terminating in a large nozzle

through which the fluids are finally discharged. The whole peculiarity of the device depends upon the funnel and its outlet; the funnel is very broad at the top, being the full width of the cushion, about seven inches in depth to the tube, terminating in the discharge pipe of the same length, which is perforated at its under side by a buttonhole for attachment, when in use, to the rim of the cushion. When the cushion is in use the rim is inflated, the discharge pipe is buttoned to the rim, and the patient is placed upon the cushion. Vaginal or rectal injections are now to be given. The fluid, as it is discharged from vagina or rectum, accumulates on the floor of the cushion, the amount this will hold depending entirely upon the depth of the inflated rim and the size of the cushion and reservoir. When it is desired to empty it the rim is caught in the hand at the upper end, and carried with the funnel hanging downward; all fluids at once gravitate into this, but do not escape, owing to the attachment of the discharge pipe to the rim. It is then carried to the closet and the discharge pipe unbuttoned, when the fluid rushes out; it is further cleaned by allowing water to run freely through it in the same manner.

The advantages gained by this device are very great. The softness of the rubber is a great advantage over the hard bedpan, the capacity of the cushion is much greater, and may be made to vary with the size of the reservoir alone. It can thus be used for purposes for which the bedpan is entirely inapplicable. The facilities for cleansing are perfect, eliminating the chief objection to which rubber cushions hitherto in use are open. The ease of transportation is also an available feature, as when collapsed it can be rolled up and packed away in small space. It can also be used for continuous irrigation, by leaving the discharge pipe, which can be made of any length, hanging over the side of the bed, discharging on a piece of rubber sheeting which conducts the fluid into a bucket.

DR. J. PRICE said that the only matter about which any question exists, is whether Dr. Kelly has any claim whatever as the inventor or originator of the irrigation pad. Such claim he has not only set up here but elsewhere, without, he thought, a shadow of authority in fact. Introducing the instrument here he has made it legitimate matter for discussion; not only as to the merits of the instrument, but the genuineness of its authorship. About five years ago he conceived the importance of an irrigation pad or cushion, and from a design of his own, Dr. J. Madison Taylor made a drawing. The instrument, as drawn, was ordered through Kolbe. Dr. Kelly saw it not only at the instrument store, but also at his office. He there examined it and discussed its merits.

DR. KELLY was sorry that anything so unpleasant should have come before the Society, and he could only say that he had no recollection that Dr. Price ever spoke to him on this subject.

CORRESPONDENCE.

ON PERITYPHLITIS AND THE EARLY DETECTION OF SUPPURATIVE PERITONITIS FROM PERFORATION OF THE APPENDIX VERMIFORMIS.

To the Editor of THE MEDICAL NEWS:

SIR: In the recent interesting discussion on peri-cæcal inflammation held at a meeting of the Philadelphia County Medical Society and published in your journal of January 7th, there are raised among the many valuable points connected with the disease in question, two by Dr. Pepper, that have specially attracted my attention and upon which I should much like further information.

He describes in the report two classes of these cases, one where the symptoms present themselves rather sharply, and under judicious management terminate generally in resolution, or they may go after a time to the formation of an abscess, and require for their surgical relief the well-known incision of Dr. Willard Parker. Both of these varieties Dr. Pepper considers to be due to inflammation of the walls of the cæcum and the peri-cæcal connective tissue, and that in them the appendix is affected to a comparatively slight degree.

Here more light is decidedly wanted. With such cases Dr. Pepper further remarks considerable impaction of feces exists, and in so far he is in accord with Krausold, who considers such inflammation rarely, if ever, to progress to suppuration unless a perforation exists. And this is the view that the surgical profession is gradually but strongly leaning to. It is supported in this tendency by ever-increasing evidence, showing more and more clearly the rarity of cæcal perforations and the frequency of appendicitis, simple or perforative, as the origin of abscesses occurring in the right iliac fossa. Even in the slowly progressing forms of suppuration such as are described by several of the gentlemen participating in the discussion alluded to above, it can be proved by a glance at the series of 100 cases of perityphlitic abscesses undergoing operation, that were diligently collected by Dr. Noyes in 1882,[1] that a majority of these distinctly gave proof of their cause being a perforated intestine. Out of the total of 100 cases, in 40 were recognized feces, fecal concretions or foreign bodies originally lodged in the intestine, and in 14 others gas in marked quantities was observed, while in 45 only, pus was seen in various states of foulness. In only one of the cases was nothing stated as to this point. Matterstock, likewise, in 146 cases of perityphlitic abscesses found fecal concretions 63 times.

Such testimony is corroborated largely by everyone who has frequently operated for perityphlitic abscesses, and, individually, I have felt it a strong argument in favor of an early surgical interference in these cases, and have elsewhere[2] so expressed myself, believing as I do, that a perforated appendix is generally the starting place of the abscess. The latter may take place outside the peritoneum by adhesion of the appendix, formed with the parietal peritoneum, then, or at a previous slight attack of appendicitis, or it can occur among the adjacent intestines, matted together by protective limiting adhesions, thus giving rise to a veritable intraperitoneal abscess scarcely to be distinguished from the former, or, finally, the fecal extravasation may spread widely and beget a fulminating general peritonitis.

It is in connection with this latter form of the disease that Dr. Pepper has called into notice a means of diagnosis which I consider of much importance. I refer to the use of an exploring needle to detect at a period much earlier than is now possible, the presence of a general sup-

[1] Transactions of Rhode Island Medical Society, 1886.

[2] A plea for earlier operations in perityphlitic abscesses, with a case of laparotomy for perforation of appendix vermiformis, in the Medical Record of June 11, 1887.

purative peritonitis. An experience of five cases of this form of peritonitis confirms the fact spoken of in your debate, and also reported elsewhere in numerous published cases, that not only does perforative peritonitis go on with great rapidity, but that the usual symptoms of a serous inflammation may frequently be wanting. Moreover, in all the cases seen in those on whom laparotomy has been performed, as well as in those in whom an autopsy has been made, there has been found, as a rule, very slight intestinal adhesions, or none at all, but an abundant secretion of puriform fluid which often collects between the loops of the moderately distended intestines, and is always to be found in large quantities in the pelvic cavity. In two of my cases the use of a large hypodermatic needle showed pus, which the subsequent laparotomy proved to come from the general peritoneal cavity, and I had been led to the same conclusion that Dr. Pepper has, that this test, used in localities other than in the right iliac region, where the possibility of an extra or intraperitoneal abscess might mislead one, would materially aid the surgeon in his decision for a prompt abdominal section, lateral or median, as might be determined on. Similar punctures have already been resorted to along the median line for this purpose. While such a puncture or punctures, for several could be safely made, will afford evidence, when obtained, of great value, yet a positive result is more likely to occur by tapping in this way the pelvic cavity.

Dr. Pepper suggests a curved needle introduced through the rectum. It is, I judge, a safer procedure to empty the bladder and then introduce a long, slender, straight aspirator needle above the pubis deep into the pelvis. This can be done without risk to the intestines in their comparatively undistended state, and a finger in the rectum will afford some guidance, as I have proven to myself in several trials of aspiration in this region for other causes. An early resort to this means of diagnosis has been a standing order with my house-surgeon for some time past, and I cannot refrain from thinking that good will come from it. For up to this time the result following laparotomy for peritonitis caused by a perforated appendix has been nearly uniformly fatal, there being, so far as is known to me, but one undisputed case of recovery out of fifteen cases, and death has occurred mainly from the profound and rapid septicæmia which is usually produced by a fecal extravasation. Yours most truly,

Robert F. Weir.

New York, January 17, 1888.

NEWS ITEMS.

The Illness of the Crown Prince.—We are pleased to be able to state that Sir Morell Mackenzie continues to receive highly satisfactory reports concerning the Crown Prince from the physicians in attendance. The condition of the illustrious patient is still better than it was last week. Further absorption of the small vegetation which recently appeared has taken place, and the slight general thickening of the left ventricular band has diminished. There is much less secretion from the larynx, showing that the catarrhal condition of the left side, which has from time to time caused a good deal of trouble, is also greatly improved. The Prince's voice, though rather hoarse, is fairly strong when he makes an effort, but in obedience to the advice of his physicians His Imperial Highness speaks as little as possible. Whilst, therefore, reiterating the warning we have already several times given as to the imprudence of placing too much reliance on the present favorable aspect of the case, it is, we think, fairly permissible to hope for the best.

We have already called attention to the peculiarly anomalous and perplexing nature of the case, which will, no doubt, apart from all points of extra-medical interest, remain as a *cause célèbre* in laryngological literature. As showing the extreme difficulty frequently met with in the diagnosis of tumors of the larynx, we may refer to a case related by Dr. Eugene Hahn—whose authority in questions of this kind no one will deny—before the Berlin Medical Society last month. A man, aged twenty-eight years, was suddenly seized with acute spasm of the glottis, apparently without any previous symptoms whatever. The presence of a tumor being suspected, tracheotomy was performed, and the larynx was afterward extirpated. On admission an abscess associated with perichondritis of the cricoid cartilage was found, but no malignant tumor was discovered. This case, so frankly reported by Dr. Hahn, affords further justification, if such were needed, for the caution which has led the Crown Prince's present advisers to discountenance severe operative procedures, for which there was no decisive indication, while the danger directly attending them was only too obvious —*British Medical Journal*, Jan. 14, 1888.

The American Physiological Association.—On Friday, December 30, a meeting was held at the College of Physicians and Surgeons, in New York City, for the purpose of organizing an American physiological association. The association has for its object the promotion of physiological research and of social intercourse among the physiologists of the country. The association will meet as a section of the Medical Congress every three years. The meeting was presided over by Dr. S. Weir Mitchell, and many prominent physiologists from all parts of the country were present. A constitution was adopted, and Prof. H. P. Bowditch of the Harvard Medical School was elected president, and Prof. H. N. Martin of Johns Hopkins University, secretary and treasurer.—*Science*, January 6, 1888.

The German Hospital of Philadelphia.—Dr. George W. Vogler has resigned the position of Visiting Physician.

Philadelphia Polyclinic.—Dr. Alexander W. Mac Coy has been elected Professor of Diseases of the Throat and Nose at the Philadelphia Polyclinic, to succeed Dr. J. Solis-Cohen resigned.

Medical Education in the United States, for the past Ten Years.—The Illinois State Board of Health, in its report on medical education, compares the statistics of the past ten years, which show several points of great interest:

The changes noted by a comparison with the report of 1886 show a net gain of two regular schools and a loss of two eclectic schools; while the others remain unchanged. As compared with the conditions which existed prior to the enforcement of the Schedule of Minimum Requirements—that is, prior to the sessions of 1883–84—the report shows that there are now 114 colleges which exact an educational requirement of intending matriculates, as against 45 formerly—there being no change in this respect from the previous year; that 43 colleges now exact

attendance upon three or more courses of lectures as against 22 formerly—being a gain of two over 1886—and 57 others make provisions for a three or four years graded course; that hygiene is now taught in 114, and medical jurisprudence in 112 colleges, as against 42 and 61 respectively, prior to 1883. There is an increase in the average of lecture-terms from 23.5 weeks to 24.9 weeks during this period, and 114 colleges now have terms of five months or over, and 63 have terms of six months or over as compared with 101 and 41 respectively. There is only one medical college that has a course less than twenty weeks, the Medical College of Georgia.

The effect of this improvement in methods of instruction and of the higher qualifications demanded before graduating the student is best seen in the diminishing percentage of graduates to matriculates. The tables embraced in the report now cover a sufficiently long period—from 1877 to 1887 inclusive—and deal with large enough numbers—116,529 matriculates and 37,493 graduates—to give them a positive value for this purpose. Errors arising from unusual or accidental conditions are largely cancelled or diminished in importance in these aggregates, and the inferences drawn may be accepted as fairly trustworthy.

The first fact of importance which arrests the attention in this comparison is that, notwithstanding the growth of population, the total number of medical students has never yet reached the proportions attained in 1882–3. The sessions of that winter were attended by 13,088 students; of 1883–4 by 12,763 students; of 1884–5 by 11,975 students; of 1885–6 by 12,321 students, and of 1886–7 by 12,948 students. Although there was a gain last year of 627 students over the attendance in 1885–6, the aggregate in 1886–7 was still 140 less than in 1882–3.

The effect of a higher standard of qualifications for graduation is further shown in the diminishing percentage of graduates to the total number of students. In 1882–3 out of every 1000 matriculates 322 were graduated, taking both the United States and Canada and all schools of practice into the account. In 1886–7 only 294 out of every 1000 matriculates were graduated. In the United States alone in 1882–3 out of every 1000 matriculates 331 were graduated, while in 1886–7 only 305 out of every 1000 matriculates were graduated.

The Water Tanks in Passenger Cars.—A sanitary inspection of railway cars by Dr. Reed, disclosed some unsavory conditions of water supply, which he describes as follows, in the *Sanitary News* of January 14, 1888:

I cannot close this paper without referring to the water-tanks as usually found in our coaches, of which twenty and one-half per cent. were found dirty, among which was discovered one with a baby's soiled diaper in it.

Many of these tanks are placed so as to open inside of the water-closet apartment, and I am creditably informed by railroad employés, who have had abundant opportunities for knowing, that it was not an unfrequent occurrence to find babies' diapers, dirty rags, and filth of that character, dumped into the water-tanks of our passenger coaches. So frequently was this the case that some of the railroads have made their cars more recently with the water-tanks opening at the top of the car, while others have placed them in plain view in the car, where offensive articles of that character could not be so easily introduced into them without being detected.

The analysis of the water, with a few exceptions, shows that a very fair quality of water was supplied the passengers on the roads examined. The custom of dumping ice into the water should be dispensed with, and instead a water-tank used that is so constructed as to permit of the ice being packed around the outside of the water-can proper, which should be porcelain-lined, and so arranged as to be easily got at and cleaned, a great objection now to those opening at the top of the car.

While the tops to these refrigerators should not only be double, but locked on, and no person furnished with a key excepting the proper railroad employés, the latter should be held responsible for their sanitary condition.

With such an arrangement, the drinking-water could be kept clean and free from "foreign or domestic" filth, the water kept cool but not ice-cold, and at the same time free from many impurities so frequently found in commercial ice.

Prizes for Medico-legal Essays.—The Medico-legal Society of New York announces the following prizes for original essays on any subject within the domain of medical jurisprudence or forensic medicine:

1. For the best essay—one hundred dollars, to be known as the Eliot F. Shepard Prize.
2. For the second best essay—seventy-five dollars.
3. For the third best essay—fifty dollars.

The prizes to be awarded by a commission, to be named by the President of the Society, which will be hereafter announced.

Competition will be limited to active, honorary, and corresponding members of the Society at the time the award is made.

It is intended to make these prizes open to all students of forensic medicine throughout the world, as all competitors may apply for membership in the Society, which now has active members in most of the American States, in Canada, and in many foreign countries.

Physician's Names and Proprietary Medicines. — DR. WILLIAM A. HAMMOND has caused the arrest of Dr. H. H. Kane, J. F. Phillips, and F. Coleman, officers of a proprietary medicine company, for associating his name with their remedy. They had advertised in the papers that Dr. Hammond had delivered a lecture on the use and abuse of the brain, in which he strongly recommended the patent medicine in question as the proper and only thing for persons afflicted with brain disorders to use. A picture of the famous physician also accompanied the advertisement. When the doctor saw the advertisement he became indignant, as he had not mentioned in the lecture the preparation. The penalty, should a conviction result, will be imprisonment for two years and a fine of $1000.—*Pharmaceutical Era.*

M. Pasteur.—Owing to continued ill-health, M. Pasteur has thought it necessary to offer to resign his post of perpetual secretary to the Academy of Sciences; but as the eminent biologist is held in great esteem, his application has not been granted, and he has been requested to continue in office with a *locum tenens* to do his work.—*Lancet*, January 7, 1888.

Decorations for Nurses.—M. Carnot, President of the French Republic, on the last day of the old year made a

round of inspection of the various Parisian hospitals, in course of which he decorated with a knight's ribbon Mdlle. Nicolle, the school mistress at the Salpétrière, who is now in her thirty-sixth year of service, and a Sister of Charity in the military hospital of Val-de-Grâce.—*Lancet*, January 7, 1888.

Type in School Books.—A very sensible decree has just been issued by the Austrian Minister of Public Instruction, forbidding the use of books printed with small type in public schools, as short-sightedness is so prevalent amongst school children in Austria. Scientific supervision might very properly be given to school books in this country, attention being especially directed to the size of the type, length of line, and spacing of letters and lines. In the works published by the Clarendon Press no fault can be found in these respects, and, speaking generally, the school books of this country are well printed. The chief fault in German books is their adherence to the very dazzling Old English shape of the letters, which certainly severely tries the eyes by necessitating very close attention, and the evil effect of this is aided by the paper being coarse and by the light supplied being usually insufficient.—*Lancet*, December 31, 1887.

Hospital Management.—In the report of the Dublin Hospitals Commission, Dr. Corley gives the following as the essentials of success in hospital management:

"*First.* The hospital shall contain not less than eighty beds, and after five years' participation in the grant, not less than one hundred, in daily occupation throughout the year.

"*Second.* The hospital shall be open for clinical instruction, and shall have not less than fifty paying students on its books each year.

"*Third.* The hospital shall be open to persons of all creeds, without any distinction, and clergymen of all denominations shall be admitted to see patients requiring their ministrations at any hour of the day or night.

Fourth. The staff of the hospital shall be appointed without distinction of creed or the place of education, or reference to the candidate's connection with any particular university or medical corporation or hospital, and without payment of any sum of money; and the principle of promotion from the junior to the senior appointments shall be recognized as far as may be deemed compatible with the interests of the institution. No member of the staff shall hold a similar appointment in any other hospital.

"*Fifth.* The junior appointments, such as resident surgeons and physicians, shall be filled up by examination, for which any duly qualified candidate may present himself.

"*Sixth.* The hospital shall employ as nurses only such persons as have gone through a duly recognized probationary training."

Professor Purkinje.—This veteran anatomist and physiologist recently celebrated his one hundredth birthday at Breslau.

The Care of a Population.—In his third and concluding lecture at South Kensington, Mr. Galton dealt with the influences of various kinds of nurture, training, and occupation on the average vigor, longevity, and disposition of large classes of persons. He considered that the surroundings influence future generations rather than the present. With a diagram he indicated the relative proportions of early and late marriages in Germany, England, and European Russia, showing the enormous preponderance of late marriages in the first, and of early marriages in the last; considering that, when other things are equals, early marriages are followed by large families, he led up to the amusing conclusion that the "out-put" of Russian babies reached a thousand a day. From Dr. Ogle's report upon the death-rates of varying ranks, he illustrated his remark that the quality of stock varies with the status of the parents. He then proceeded to the unforeseen and wide consequences of apparently small reforms, instancing the smallness of families in France since the law regulating the equal division of property. In strong terms he then dealt with the prevailing want of statistical imagination and our consequent carelessness as to undoubted social duties, considering that the marriages of phthisical persons should be prevented by public opinion, if not by more stringent measures. He thought that obvious sanitary neglect should be treated as manslaughter, and that legal restraint should check the pursuit of any line of conduct whose average ill effect has been ascertained. In approving terms he referred to the establishment of professorships of physical culture at Amherst and Harvard Colleges in America, and quoted from a correspondent at Wellington the opinion that the "cultivation of man as a whole, and not only in part," should be encouraged by the bestowal of degrees. In New Zealand it would appear that a prize has already been awarded to the "best-made man." Of the value of gymnasia in the hands of medical men rather than of professional atheletes, and of the importance of more rigid school hygiene, he also spoke enthusiastically. In conclusion, he gave a brief retrospect indicating his belief in the theoretical possibility of raising the standard of the race by a study of the influences that tend to *eugenism*, a word implying goodness in birth and in rearing.—*Lancet*, December 17, 1887.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING JANUARY 21, 1888.

Goldsborough, C. B., *Surgeon*.—To proceed with insane seamen from Chicago to Government Hospital for the Insane, January 16, 1888.

Heath, F. C., *Assistant Surgeon*.—To proceed to Buffalo, N. Y., for temporary duty, January 21, 1888.

Stoner, G. W., *Surgeon*.—To proceed to Wilmington, N. C., Georgetown and Charleston, S. C., Savannah and Brunswick, Ga., Fernandina, Jacksonville, and Pensacola, Fla., as inspector, December 30, 1887. (Omitted from previous lists.)

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

ORIGINAL LECTURES.

KNOCK-KNEE AND BOW-LEGS, WITH REMARKS UPON RACHITIS.

Two Clinical Lectures Delivered at the Philadelphia Hospital.

BY A. SYDNEY ROBERTS, M.D.,

LATE SURGEON TO THE HOSPITAL, INSTRUCTOR IN ORTHOPÆDIC SURGERY IN THE UNIVERSITY OF PENNSYLVANIA, AND ORTHOPÆDIC SURGEON TO THE OUT-PATIENT DEPARTMENT OF THE UNIVERSITY HOSPITAL, ETC.

LECTURE I.

GENTLEMEN: As Macewen, of Glasgow, and others, have, by the revival of the operation of osteotomy for the cure of knock-knee and bow-legs, renewed the interest in these deformities, and place themselves on record as being ardent advocates of operative procedures for their radical relief, it will be my endeavor to call your attention especially to these important malformations; and I purpose to inquire how far operations are a necessity for their correction, and what proportion and class of cases can be best treated by such means, and, also, whether mechanical methods of treatment are not fully as important as those of a more radical nature.

Mechanically considered, knock-knee and bow-legs result from an alteration in the plane of the articulating surfaces of the bones entering into the formation of the knee-joint, with or without a curving of the shaft of the femur or tibia, whereby the knee is thrown either inside or outside a perpendicular line let fall from the head of the femur to a point midway between the two malleoli. Should the knee fall inside this line, the resulting deformity is known as knock-knee or *genu valgum*, the opposite condition, that in which the knee is without the perpendicular, being called bow-legs or *genu varum*, and the causes producing these results may be summarized as: 1. Rachitis. 2. Ligamentous relaxation. 3. Central disturbances destroying the equilibrium of muscular action, or affecting the nutrition of the epiphyses.

By far the most frequent and important cause is the one first mentioned: namely, *rachitis*, which favors the production of deformity by the softening of bone and the relaxation of ligaments which occurs during its progress, whereby we have an alteration of the normal development of the cartilage and periosteum from increased cell proliferation, the resulting cartilaginous and osseous tissues being less completely matured, and much more retarded in their development than in the normal course of bone growth. Moreover, the rapidly proliferated cells are not supplied with a sufficient quantity of inorganic elements, and, therefore, a relative excess of organic material with a corresponding deficiency of lime salts occurs. In other words, the cells which are deposited are immature, half ripe in character, and the dyscrasia interferes with their normal progression toward maturity. When the disease finds expression in the epiphyses, it occurs at the epiphyseal juncture, at which point we find the cartilage filled with young cells which are neither mature cartilage cells nor true bone cells, but have a character which partakes of both. In consequence of this abnormal cell deposit we find the thickness of the cartilage is increased, and the structure has not the resisting quality so marked in health; on the contrary, the aggregation of cells forms a soft, non-resisting material which breaks down and gives away under pressure, and if this pressure be unequally distributed, bending of the bones and alteration of the plane of the joints result.

Rachitis is, primarily, a constitutional disorder, whose local manifestations fall with greatest force and frequency upon the organs of locomotion and support, the bones, epiphyses, articular surfaces of the joints, the ligaments, and muscles. The osseous changes found are due to increased vascularity of the periosteum and other nutritive centres, the epiphyses, and medullary substance. Rachitis is a disease of early childhood. Cases in which it is congenital have been reported, and knock-knee and bow-legs have been observed in the newborn. The disease most usually begins about the period of dentition, and is attended by disturbances in the alimentary tract, vomiting and chronic diarrhœa being frequent. The patients suffer also from sweating of the head, face, and neck, and prefer to lie quietly, resisting attempts to move or handle them. With this, notable weakness and marked tenderness are observed, and this weakness, noticeable chiefly in the muscles, sometimes give rise to a condition which has been mistaken for infantile paralysis, although no palsy exists. Whilst some children suffering from rachitis appear fairly well nourished, the majority have a large belly, and a puffy, flabby condition of flesh, easily distinguished from the firm, resistant feeling of healthy tissues. They are also peculiarly liable to convulsive affections, as before mentioned, and chronic hydrocephalus occurs frequently. Thirst is at times urgent; the patients sit or lie about; are silent or drowsy, and at night often rest upon their hands and knees, with their heads buried in the pillow, or toss restlessly from side to side.

Whilst these symptoms are progressing, notable changes are going on in the bones, muscles, and ligaments. I have already alluded to these changes in my general remarks on pathology, and have shown you how their chief expressions are found in the epiphyses and shafts of the bones. Clinically, it is not, however, alone in the long bones that the changes take place. The skull, with its thin and softened envelope and thickened sutures; the thorax, as shown principally in the beaded ribs, chicken-breast, and curved vertebræ, and the flattened, distorted pelvis, all bear evidences of the disease. Not all the cases, however, exhibit these universal effects of the general condition. Indeed, I have seen undoubted evidences of localized rachitis, where the disease, so to speak, had expended itself upon one locality. Thus, it is not unusual to see deformities which are unilateral in character, and one-sided cases of bow-legs and knock-knee are not uncommon. We have already

spoken of the causes which produce this condition, and will only add that, although it is found more frequently amongst the poorer classes, the wealthy are by no means exempt from it. Poor sanitary surroundings, insufficient nourishment, lack of air and sunlight, and the crowding together of many people, frequent pregnancies, and the bringing up of children "by hand," all add their quota as active agents in its production. Locality and climate also have their influence as causative factors. Thus, it is by no means a common disease amongst American children, but is very frequent in Southern races, the negro being peculiarly liable to it; and its frequency in England has caused the Germans to give to it the appellation of "*Englische Krankheit.*"

I have dwelt at length upon the general manifestations of rachitis, as it is in this stage, before local symptoms have developed, that general treatment may prevent deformity. In beginning the treatment, great care should be exercised in the selection of appropriate diet, and all errors in this and the surroundings of the patient should be corrected. The child should be regularly taken out in the open air, and "sun-baths" given. Attention should be especially directed to the proper bathing of the child, and the skin kept in good condition by these means. The diet should be digestible and nutritious, and all approved methods having for their object the proper hygienic care of the patient should be persistently and systematically employed. As to drugs, those which are directed to checking the diarrhœa after the bowels have been emptied of irritating matter are first indicated. The time-honored "rhubarb-and-soda" mixture will best accomplish the latter purpose, while drop doses of tincture of opium, with the addition of an alkali, have best succeeded in my hands in checking the diarrhœa. To improve the general condition of the child, cod-liver oil may be given, and by many it is considered a specific; but there are many objections to its use: it is apt to increase the digestive trouble, and many children cannot be induced to take it, no matter how disguised. Good, fresh butter answers admirably as a substitute, and fulfils all the indications of the oil. The compound syrup of the hypophosphites is another excellent remedy, and is readily administered for a long time. Iron is an efficient tonic, especially the syrup of the hypophosphite or the iodide. Phosphorus also has given excellent results in this as well as other wasting diseases of the bones. Such is a brief outline of the medicinal treatment of rachitis, important in all cases of the disease, but important in cases prior to the occurrence of deformity, in addition to which mechanical supports should frequently be used as a prophylactic measure. The case I now show you will illustrate this principle:

Case I. *Softening of the bones from rachitis; retention braces; improvement.*—J. M., æt. twenty-six months. The hereditary history in this case good, as to bone, joint, or lung troubles; she was apparently healthy until her eighth month, when her mother was obliged to leave her to the care of strangers. At this time it was noticed that she was not as lively as usual, had frequent diarrhœa, was peevish and restless at night, sweating freely, frequently soaking the pillow. She has never attempted to walk, but can hold herself erect by the aid of chairs. You will notice the flabby condition of the muscles, although she is apparently fairly nourished, and although presenting all the characteristic symptoms of rachitis, the large head, protuberant belly, and flattened epiphyses indicate rachitis, there is, as yet, no evidence of deformity of the lower extremities, for the child has not yet walked, and nature has evidently acted in a conservative manner, by depriving the muscles of their proper tone, thereby making it impossible for the child to throw the weight of the body upon the lower extremities, and we have happily the power to prevent, by mechanical means, the occurrence of deviations which would surely follow were the softened osseous tissues allowed to bear unaided the superincumbent weight of the body.

In this case the object has been accomplished by the application of retention braces, consisting of two steel uprights fastened to the shoe, and extending above the knee, with joints corresponding to the articulation of the knee and ankle. These allow free motion, but at the same time remove the superincumbent weight. To one point I wish especially to call your attention: when I grasp the thigh and leg of the patient, and move the knee-joint from side to side, you can easily distinguish the preternatural lateral mobility of the articulation, a common condition in rachitic subjects. This is due to ligamentous relaxation, and opinions vary as to the ligaments involved, and their action in the production of the deformities, it being considered by some that primary relaxation of the internal lateral ligament results in a separation between the articular surfaces of the knee-joint upon the inner side, allowing increased growth of the internal condyle downward and inward in the gap between its lower surfaces at the head of the tibia, while others are of the opinion that shortening of the external lateral ligament, by permitting pressure to be exerted upon the external condyle, prevents its normal growth, the internal condyle, at the same time, completing its development. While some cases occur in which ligamentous relaxation seems to be the only *apparent* cause of the deformity, they are extremely rare, and I think that the relaxation, as a rule, is secondary to, and symptomatic of, the bony changes. While much attention has been given to the external ligaments of the knee-joint as factors in the causation of knock-knee, I am sure that the *internal* ligaments of the joint, principally the *crucial*, are largely concerned in the deformity; but as to the mechanism of these ligaments as causative agents, I cannot, for want of time, enter. In the small class of cases which exhibit no evidence of rachitis, but which suffer from relaxation of ligaments, the term atonic can best be applied. They are similar to the class of lateral spinal curvatures known as habitual or functional; but, as before stated, in the majority of cases the ligamentous changes are secondary to the osseous ones, and depend upon the general condition—*i. e.*, *rachitis*.

The changes which occur in the bones, and which lead to the deformity, may be divided into three stages:

1st. The stage of vascularity, or invasion.

2d. The stage of softening, or deformity.

3d. The stage of consolidation, or sclerosis.

It is important that these stages should be recognized, as giving important indications for treatment. The second stage is well illustrated in the case before us: when I grasp the limbs, and attempt to bend the bones, a characteristic springy sensation is imparted to the hands, showing that the stage of softening is still in progress, and indicating that constitutional and mechanical treatment are sufficient.

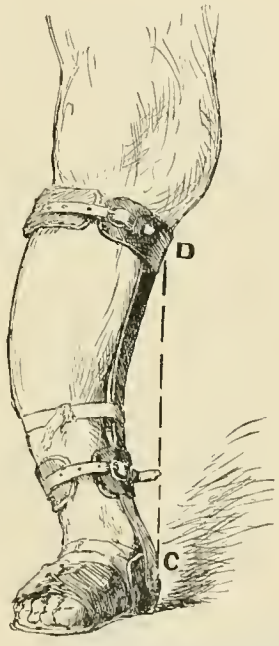
When softening has further progressed, and deformity has begun from the weight of the body upon the diseased tissues, mechanical support may still suffice; but when hardening or sclerosis has once occurred, and the bones are in a deformed position, nothing but operative measures will restore the limb to its normal position. To determine this stage in doubtful cases, I use an instrument which I look upon as an important aid to correct diagnosis, *i. e.*, the ordinary bone drill, preferably, the cog-wheel drill of Colin, of Paris; the procedure is analogous to exploratory incision prior to other surgical operations. Where the drill encounters no obstacle to its entrance into the bone, and imparts to the hand the sensation indicative of soft tissue, operative procedures are not necessary, but, should the characteristic resistance of the sclerotic stage, as if the drill were being bored through ivory, be met, mechanical measures will be futile, and operation is necessary.

I have an opportunity of showing you another case illustrative of the stage of softening with beginning deformity.

CASE II. *Bow-legs from rachitis; mechanical support; improvement.*—This patient, Mary W., is three years old; gives all the evidences of having had rachitis, and still shows symptoms of what may be called the subacute stage. You notice many of the conditions to which I called your attention in speaking of the child who has just passed out, but, in addition to these, you are at once struck with the peculiar waddling gait, and the tendency of the feet to a varus position when the child attempts to walk. This varus is not constant, as in some cases of bow-legs there may be a valgoid position of the feet. Here you again see the unusual lateral mobility of the knee-joints. In the present instance the deformity, which is quite marked, is produced by curvatures affecting both the femur and the tibia: that is to say, the rachitic process has involved the diaphyses above and below the knee-joint. This is not, by far, as common as those cases where the tibia is alone affected, in which case the deformity usually takes place at about the middle of the tibia, although the same condition, greatly magnifying the distortion, may occur at the lower third, or an anterior curvature of the tibia may be observed. When I grasp the bones firmly, I at once get a peculiar springy response, and this serves as a guide to my treatment in this stage. In answer to inquiry concerning the increase of the deformity, the mother states that the bowing has increased very rapidly during the last four or five months; that before this it was not at all marked, and she has experienced no fear of a permanent deformity, having been told by a practitioner that the child would surely grow out of it. This is a popular fallacy, and cannot be too strongly condemned. The indications for mechanical treatment are therefore very plain. In order to counteract the effect of the superincumbent weight, which falls on the lower extremities during the day in the act of walking, it becomes necessary to have something which shall relieve this, and, for this purpose, I use the conventional apparatus which I briefly described in speaking of the first case. This brace will allow your patient to go about at the minimum risk of increasing the deformity, and also give him an opportunity to get sunlight and fresh air, very important adjuncts toward improvement of his general condition. In cases in which deformity is present, this serves merely as a retention splint, and something more powerful must be used to overcome the deformity.

The brace which I have advised for the application of elastic traction, has, in my hands, in private and hospital practice, accomplished excellent results. It consists of a piece of straight tempered steel, its upper extremity terminating in a semi-circular steel band to extend half way around the limb; below, and jointed to it opposite the ankle is a steel foot piece with heel cup, which is secured to the foot by a strap passing over the instep, and a light leather shoe-piece laced over the foot. The length of the upright is regulated by the position of the curvature in the bones: in bow-legs where this occurs in the tibia, the upright should, therefore, extend only to its upper border. The brace is adjusted by securing it to the internal aspect of the limb, and the elastic element of the brace brought into play by strapping the steel upright to the leg at the point of the greatest convexity.

FIG. 1.



(Fig. 1.) It should be thus applied at night, and it is readily seen that its constant effort to return to the straight line D C exerts a continuous elastic force in a direction calculated to reduce the deformity.

ORIGINAL ARTICLES.

NEPHROLITHOTOMY.

BY D. HAYES AGNEW, M.D.,
PROFESSOR OF SURGERY IN THE UNIVERSITY OF PENNSYLVANIA.

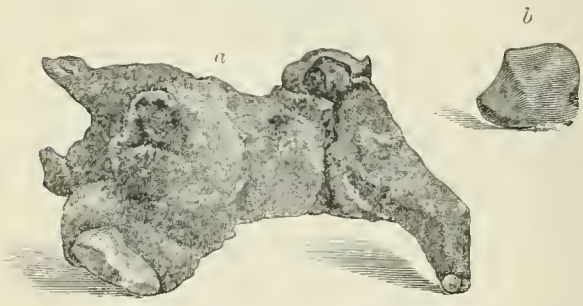
MR. S. W., aged thirty-eight, a resident of Sydney, Nova Scotia, was brought to me by Dr. McPherson, of that place. Mr. W. had enjoyed perfect health until May, 1876, when he was overtaken with a severe attack of acute rheumatic fever, lasting, in a modified form, for nearly six months, and leaving him with an ankylosed knee-joint. The year following, the fall of 1877, he had a

severe paroxysm of what was regarded as renal colic, and every succeeding month for five months, similar attacks were experienced, lasting seldom less than twenty-four or forty-eight hours. From this time until 1879, he enjoyed a complete immunity from pain, but after this long exemption was again seized with another paroxysm of unusual severity and duration, which confined him to his bed for an entire week. During all this time, no calculi were passed, and comparatively little vesical irritation was experienced.

From this period onward, until September, 1887, he continued in fair health, experiencing, however, at irregular intervals, more or less pain in the left lumbar region, seldom lasting over half an hour. It was now that the urine became quite turbid. In October, the pains in the left lumbar region became more severe, scarcely ever intermitting. These pains were not confined to the left lumbar region, but extended over the entire left side of the abdomen, reaching in not a few instances to the right loin, also shooting down the left thigh, and into the left testicle, accompanied by strong retraction of the gland.

About the latter part of October, the urine became thick, ropy, and offensive, and the old pains almost unendurable. This condition was again followed by a notable abatement of pain, and a marked improvement in the appearance of the urine.

At the time the patient arrived in Philadelphia, which was the last week in November, he was again beginning to suffer from the lumbar pains, attributed, and perhaps correctly, to the effects of the long journey from Sydney to this city. The urine, on examination, was found to contain a considerable quantity of pus, blood, and some renal epithelium. The diagnosis was stone in the left kidney, and the operation of nephrolithotomy recommended. To this the patient readily assented, and on December 1st the left loin was opened by the usual incision, the adipose tissue around the kidney broken up, and



Renal calculi (less than natural size).

a stone detected by the touch in the pelvis of the organ. On opening the pelvis, a considerable quantity of offensive pus and urine escaped. The stone proved to be one of great magnitude, not only filling up the pelvis of the gland, but sending prolongations into the infundibula (*a*). After its abstraction, a second concretion (*b*) was detected in the ureter, and removed, the two weighing 473 grains. A large sized drainage tube was introduced through the wound into the pelvis of the kidney. After washing out the parts thoroughly with a solution of the mercuric chloride (1 to 1000), the incision was closed by two rows of sutures, the deep ones, consisting of catgut, brought together the lumbar aponeurosis, and the superficial ones, of silkworm-gut, inclosed the integument, subcutaneous tissue, and muscles. The external dressing was composed of the ordinary antiseptic materials. A portion of the drainage tube was removed on the thirteenth day, and the remainder on the nineteenth day. On the thirteenth day, the patient was allowed to sit up in bed, and on the eighteenth day was moving about his room. From the time of the operation until he left the hospital for his home, he was literally without an untoward symptom.

SIX CASES OF INJURY TO THE SHOULDER, FOLLOWED BY PARALYSIS.

BY GUY HINSDALE, M.D.,

ASSISTANT PHYSICIAN TO THE INFIRMARY FOR NERVOUS DISEASES, PHILADELPHIA.

Paralysis of the arm following injuries about the shoulder-joint has long excited the interest of both surgeons and neurologists. In those instances where luxation has occurred, stretching or laceration of the branches of the axillary plexus is usually assigned as the cause of the paralysis, but cases are met with in which the humerus has not left its socket, and yet paralysis of the arm of very serious nature follows a blow. To account for this it is necessary to look to something else than the head of the humerus. It is possible that the brachial plexus may be bruised by forcing the clavicle upon the first rib, at which position the nerve trunks are liable to be compressed.

The first of the following cases seems to be a good illustration of this affection.

Case I.—Peter R., æt. fifty-nine, was admitted to the Infirmary, April 15, 1887, under the care of Dr. S. Weir Mitchell. He was perfectly well before the present trouble. Fourteen months previously he fell down a flight of eight steps, and struck the point of the left shoulder on the leg of a turning lathe. He was unconscious for a few moments. The arm instantly became useless, but was not painful. Sensibility was lost from the fingers up to the neck. It was a month before he could bend the fingers; he then could move them slightly. Apparently all the cords of the brachial plexus were affected. There was no dislocation or fracture of any bone.

Fourteen months after the accident the condition was as follows: *Motion:* Can pronate the forearm, but cannot supinate completely. The fingers and hand are normal; grip powerful. Extension of the arm: triceps, fair; biceps, nil; pectoral muscles, fair: suprascapular, infrascapular, and deltoid, nil. Trapezius and levator anguli scapulæ, fair. The wasted condition of these muscles and the apparent luxation of the shoulder-joint are very noticeable. Two fingers could be laid in the sulcus between the clavicle and head of the humerus. *Sensation* unim-

paired. Faradism produced in the deltoid only slight fibrillar contraction; in the infra- and supra-scapular, nothing. In the pectorals, trapezius, levator anguli scapulæ, rhomboid, latissimus dorsi, and triceps, a good response. Galvanism produced no action in the scapular muscles. In the triceps it was lessened, but no serial alteration.

Galvanism was ordered three times a week, eighteen to twenty milliampères, with daily massage; a hypodermatic injection of one-fiftieth grain of strychnia was given every other day. The arm was also placed in a sling, with a rubber supporting band, so as to hold the humerus up and relieve wasted and fatigued muscles. It is proper to say that galvanism and strychnia had been given him during several months of previous treatment at the University Hospital Dispensary for Nervous Diseases.

Three months in the wards of the infirmary, and five months attendance at its dispensary have done a great deal for this man. At first he could not use his fingers; could hold nothing in his hand; he could barely move them. His grip was very weak. He is now able to dress and feed himself, and the motions are greatly improved, though the supra- and infraspinati, biceps and triceps, are much wasted. Burq's dynamometer shows sixty-three in the right hand, and fifty-three in the left. The arm has gained three-eighths of an inch in circumference in the last three months.

CASE II.—P. E. C., æt. sixty-six, a clerk, was admitted to the hospital June 13, 1887, under Dr. Osler. He was injured eight weeks previously in an altercation in which two men fell upon him, and the right shoulder was dislocated. This was restored after twenty-four hours under ether by traction with the foot in the axilla. For this purpose, the operator's shoe was removed. No bones were broken; the shoulder was swollen, and extremely painful. A Velpeau dressing was applied for ten or eleven days. Motion of the fingers and of the hand was completely lost at the time of the accident, and has never been restored. The forearm could be moved a little after the accident, but motion is now lost. The arm cannot be moved freely.

Electrical examination. Faradic current: no response in any of the muscles of the arm, except in the triceps, where it is moderate, and in the extensors and flexors of the carpus, where it is slight. *Galvanic current:* reaction of degeneration marked in the deltoid and biceps, also in the extensors and flexors of the forearm. In the latter muscles it is very slight.

Pain is now present in the arm, especially so when the patient is overheated. The fingers are swollen and œdematous.

Dr. Osler directed massage and a descending galvanic current to be applied. At the end of one week, the reaction of degeneration remained. At the end of six months, motion is greatly improved, and all the muscles have increased in size. The œdema has entirely disappeared.

CASE III.—Perry M., of Ontario, æt. nineteen, applied at Dr. Osler's Clinic in September, 1887. Two and a half years previously he was struck by ice falling from a roof. The blow was received on the back and left shoulder. He was unconscious for fifteen minutes. A surgeon who examined him said that no bone was broken, but the left clavicle was dislocated at the sternal end, and touched the right clavicle. The skin was not broken or bruised. The patient became delirious, and was very ill. Sensation was entirely lost at first, but is now partially restored. He has never used the arm since. Motion is very slight in the biceps, in the deltoid it is gone; the pectorals move slightly. The fingers can be very slightly flexed. The wasting of the shoulder-girdle muscles and forearm and arm is extreme.

Electrical examination shows a slight response to faradism and galvanism.

CASE IV.—Wm. D., æt. forty-eight, applied for treatment three or four weeks after a fall, in which his left arm was under him. This gave him pain in his elbow and shoulder for one week; after this he lost power in the wrist and hand. On application, the arm and shoulder were found greatly wasted. He had great difficulty in placing the hand on the back of the neck, and was unable to extend the wrist or the thumb. A slight tap, however, over the musculo-spiral nerve caused extension of the wrist, and the slightest tap over the deltoid caused fibrillar contractions. The patient had pain on the right side of the cervical spine, extending up to the head. Wet cups were applied to the back of the neck and over the painful nerves every other day for a week. Three or four ounces of blood were taken each time. A blister, three by four inches, was then applied to the cervical spine.

In one week, the patient was able to extend the wrist better than before. At the end of two weeks, the cautery was applied to the neck, and ten grains of iodide of potash were given *t. i. d.*, and the patient continued to improve.

CASE V.—Hugh G., æt. sixty, under Dr. Sinkler. While carrying two buckets of water five or six months before applying for treatment, fell, striking his right shoulder and wrist. No bones were broken. The limb remained swollen and painful for three or four weeks, and was painful at the time he came to the hospital. The forearm and hand during the previous two months had wasted.

On examination, the muscles of the hand, forearm, and arm were found to be decidedly atrophied. All the movements of the arm, forearm, and wrist were preserved: the latter movement caused pain. Flexion and extension of the fingers were stiff. He could make a fist. The fingers were contracted and could not be extended fully. He could not abduct or adduct the fingers or thumb. Loss of sensation to compass points in all fingers. He localized sensation well. There was hyperæsthesia of the palm of the hand. Dynamometer: R. 60; L. 100. The electrical conditions were as follows: Lessened reaction to galvanic and faradic current in the right forearm; normal in kind. In the hand, no reaction to faradic current. The anodal opening and cathodal opening contractions were not obtained. The anodal closing was slightly greater than the cathodal closing contraction. The galvanic current was ordered three times a week.

Case VI.—Thomas H., fell about fourteen feet, three months before applying at Dr. Sinkler's Clinic for treatment. He struck on his head, cutting it, and bruising his shoulder. A scar, one inch in length, was seen over the left parietal bone. Consciousness was lost for half an hour after the accident, after which paralysis of the left arm and left side of the face was observed.

At the end of six weeks the face was much improved, although shortly after the accident the left eyeball became apparently shrunken, and withdrawn into the socket. One month later pain occurred in the ulnar distribution of the left arm, extending gradually to the extremity. At the same time a "shivery feeling" was experienced down the left arm, if the left side of the face and ear were particularly twitched. At the time of examination, pressure made over a sensitive spot just above the sternal end of the clavicle, caused a thrill in the hand and arm. Severe pressure caused pain.

The following condition was recorded by Dr. Sinkler: On inspection the arm and shoulder were much atrophied. The head of the humerus gave the *appearance* of dislocation. The deltoid was gone; the pectorals much wasted. There was a patch of anæsthesia two inches above the elbow, covering an area five by two inches, on the external aspect of the left arm. Hyperæsthesia of the surface over the pectoral muscle; no sensation below the elbow. The hand appeared shiny. A tap over the muscles of the arm and forearm caused a reflex; over the pectoral, pain. A water blister had appeared on the outer surface of the end of the middle finger. The left arm was hotter than the right; there was no spot painful to pressure on the arm. A needle prick on the outside of the arm causes a small cup of goose-flesh around the prick, and bleeding is slow. A prick on the end of the fingers bleeds occasionally, although the hand is congested. After a few minutes the point where the needle was inserted presented the appearance of a small wasp sting.

The treatment which Dr. Weir Mitchell relies upon in all of these cases of atrophy and muscular paralysis consists of galvanic or faradic electricity, manipulation, and alternate hot and cold douches, with a subcutaneous injection of strychnia, one-sixtieth of a grain, so that the groups of spinal ganglia, which have long been inactive, may be given a special increase of irritability. It is not necessary that the injection should be made into the palsied muscle.

Electricity may be employed so soon as the acute symptoms attendant on the accident have abated. By this agent nutrition is maintained; a fresher and larger blood-supply is brought to flaccid muscles than if left to voluntary movement. The current to be chosen is the one which best moves the muscles. The galvanic current interrupted or reversed rapidly in the strength of six to ten milliampères will, in bad cases, have to be depended upon when faradism fails. Even in these cases, after a course of galvanic treatment, the muscles may be found to be responsive to a strong induced current, which may then be substituted. A faradic battery, though apparently without power to move a single palsied muscle, may yet do great good, if patiently used. Daily applications of the primary current for from fifteen to thirty minutes will often increase the bulk and warmth of a limb before irritability of the muscles is perceived, and should encourage to further effort.

At the outset, when the reaction of degeneration is met with, or when no reaction at all obtains, everything should be done to favor contraction. The tissues themselves may be soaked in warm salt water, and while yet warm, the electrodes covered with absorbent cotton moistened in hot salt water, should be applied. In this way the skin is reddened, conduction becomes easier, and the muscle response improves. Pain would be an indication for the use of a lesser current, and if neuralgia should supervene, electricity would have to be suspended for a time. This, however, would be an encouraging sign.

Nélaton, who has described this class of cases, took a very unfavorable view of them, but with better means at our command much more can be accomplished than in his day.

ARACHNOID CYSTS OF THE BRAIN.[1]

By EDWARD T. BRUEN, M.D.,
ASSISTANT PROFESSOR OF PHYSICAL DIAGNOSIS IN THE UNIVERSITY OF PENNSYLVANIA.

Case I.—Mary C., æt. thirty-two, died in the Philadelphia Hospital September 21, 1887.

Autopsy.—On removing the dura mater, four cysts were found situated upon the cortical portion of the brain. There were two cysts on each side of the median fissure; those on the right side were irregular in shape, and each somewhat larger in size than a walnut. They were situated mostly over the occipital lobe, but the outer one particularly extended over a portion of the parietal lobe. On the left cortex, the cysts were much larger; the one close to the longitudinal fissure partly covered the occipital and parietal lobes, and was three inches in length by an inch in diameter. The outer and smaller cyst occupied a position over the occipital lobe, but extended somewhat over the parietal lobe. The walls of the cysts were composed of thin lamina of membrane, and contained a clear fluid.

Owing to the pressure occasioned by the cysts, extensive atrophy of the convolutions of both occipital lobes had occurred, but upon the left side the convolutions of the superior portion of the parietal lobe had been decidedly involved in the atrophy consequent upon the pressure. This process was so marked that the surface of the left cerebrum was depressed half an inch below that of the right, and the entire left hemisphere occupied by the cysts appeared distinctly smaller. The close

[1] Read at the College of Physicians of Philadelphia, January 4, 1888.

proximity of the cysts upon the left side to the fissure of Rolando shows that the motor tract on this side of the brain must have been subjected to irritation by pressure during the development of the cysts.

This specimen has two special aspects of interest, the pathological and the clinical. Considered from the standpoint of pathology, I incline to think the cysts were congenital, because they were bilateral, and associated with marked atrophy of the cerebral convolutions.

The cysts may have originated from extravasation of blood into the sac of the arachnoid. The cause of such extravasation may be difficult to explain; but instrumental deliveries in childbirth have been supposed to share in determining this condition, and the same may be said of falls or blows received on the head in infancy.

The following case, taken from the Reports of the Norristown State Hospital for the Insane, 1885, seems an example of large arachnoid cyst from extravasation of blood:

Autopsy, eight and a half hours after death.—On raising the calvarium, which exhibited nothing unusual, two large hematomata were found, completely covering the superior aspect of the hemispheres—that is to say, they completely filled the vault of the calvarium. The walls of the sacs were quite firm, and they contained a dark bloody liquid. They separated easily from the dura, and were in no way attached to the pia. The pia was slightly opaque and thickened. The diameter of the sacs at their thickest portion was upward of an inch. The convolutions of the brain were small and shrunken. On section, the gray matter appeared thin on the upper surface of the convolutions, but normal in the depths of the sulci. The substance of the brain was firm. The lateral ventricles showed slight reddening of the ependyma.

Microscopic examination of the cortex revealed no change beyond an apparent decrease in the number of cells in some places, and a slight general increase in the neuroglia.

Arachnoid cysts are seldom observed in a recent state, and from their usually having existed for a long period before they are examined, the effused blood is found to have already undergone considerable modifications. The fluid usually is thin, clear, and serous. The walls of arachnoid cysts are commonly adherent to the dura mater by loose adhesions, and are at first brown and rough, even laminated, becoming in lapse of time smooth and polished.

The pressure of such cysts upon the cerebral hemispheres may produce atrophy of the convolutions, as in the case under consideration. The pressure of arachnoid cysts sometimes may so diminish the thickness of the parietal bones as to cause a local bulging tumor known as external, partial, or local meningeal hydrocephalus. It is possible for the entire arachnoid sac to become one large cyst. There is a specimen of this so-called external or meningeal hydrocephalus in the Wistar and Horner Museum at the University of Pennsylvania.

It is interesting to note that arachnoid cysts may contain concretions of cholesterin, cholesteatoma, and the scales may be interwoven with extremely fine microscopic hair. Even small plates of bone have been described in the walls of these cysts.

Arachnoid cysts must not be confounded with cysts due to extensive loss of substance in the interior of the brain, whether due to hemorrhage, softening, or inflammation which leads, after absorption of the detritus, to the formation of cavities which are generally filled up in part by clear or turbid liquid. This special state of the brain has been described as the Gruyère cheese condition, or état criblé, because the softening occurs in small patches, and the little cavities, when numerous, give the tissue a cribriform or sponge-like appearance.

Ziegler states that when softening has occurred round a small arterial branch, the space left vacant on absorption of the products of disintegration is often filled up by an accumulation of liquid in the adventitial lymph channel belonging to the vessel, which latter then looks as if it ran through a wide lymph-sac, resembling that caused by simple localized lymphatic stagnation or engorgement. When such cysts are large, and lie just under the pia mater, or at least not very deeply, the overlying tissue in general sinks in and leaves a sub-pial or sub-arachnoid space, which soon fills with liquid (see also monograph by Kundrat, "Porencephalie").

The chief interest pertaining to Case I. relates to its clinical history:

The patient had been the subject of occasional epileptic convulsions for twenty years. She passed four years in the Insane Department of the Philadelphia Hospital when she was twenty-four years of age, and during the last two years she has been at intervals an inmate of the wards for nervous cases in the Philadelphia Hospital. When I first saw the patient she was suffering from violent spastic contractions of the extensors of the arms and hands, legs and feet. The head was frequently violently retracted and fixed in full extension, with the face turned to the right side. The muscles of the lips and mouth were not markedly affected, but the speech was hesitating, and articulation imperfect. The spastic contractions of the muscles were not constant.

The clinical history during the four weeks she was in my wards was marked by a febrile movement of the continued type, typical of typhoid fever. The typhoid state was present, also diarrhœa. Indeed, the diagnosis of typhoid fever was entertained as the most probable interpretation of the febrile symptoms, and at the autopsy the characteristic enteric lesions of typhoid fever were discovered.

During the progress of the case, it may be noted that there was conspicuous absence of symptoms pointing to inflammatory disease of the cerebral membranes, while, on the other hand, the spastic contractions, and the retraction of the head and neck already mentioned, rendered probable the suspicion of central cerebral mischief, since local spasms, which

go under various names, such as cramps, twitchings, epileptoid attacks, athetosis or athetoid movements, are common symptoms of the morbid growths which affect the cortical motor area.

I have received from Dr. Wharton Sinkler the following notes of a case which has recently been under his care. The symptoms were so similar to those which I have described in the case which forms the basis of this paper that it seems probable that there are lesions in the same region, possibly also of a cystic character.

Case II.—John S., æt. forty-four years, married. Occupation, "steam packer." Applied for treatment at the Orthopœdic Hospital and Infirmary for Nervous Diseases, August 29, 1887. He has always had good health except attacks of rheumatism. Denies syphilis, and says he has been temperate. About two years ago he had an attack of a convulsive nature while at work. It was attributed to excessive heat. After this attack he worked for eight or nine months, when he had another, and, after the convulsive seizure on this occasion, he continued to shake all over for several hours. Two weeks later he had a third attack, and since then he has not been able to work. The trouble was a general trembling, with unsteadiness of gait, and at times the face and left leg were more affected.

Present condition.—The patient walks with extreme unsteadiness, due to almost complete want of power of coördination. The walk is like that of an ataxic. When he attempts to walk, the arms are thrown about in various directions, and the fingers open and shut spasmodically, assuming the various positions seen in athetosis. While sitting there are occasional twitches of the left leg, but otherwise the limbs are at rest. The face, however, undergoes remarkable contortions, first one side and then the other. These spasmodic contractions of the facial muscles are most marked if he attempts to speak. The speech is much affected. There is no aphasia, but the words are jerked out in an irregular and hesitating way, but he does not use the wrong words. His mind is not impaired to a marked degree, but he is less intelligent than formerly; he is able to read; the movements of both hands are incoördinate, and he feeds himself with much difficulty. Dynamometer: R. 100; L. 50; knee-jerk exaggerated on both sides; ankle clonus present. The eye-ground was examined by Dr. de Schweinitz, and no anomalies were found.

The patient was admitted to the hospital and remained for several weeks. At first he had two or three convulsions, in which he rolled out of the bed, and was unconscious for a short time. He was given iodide of potassium in increasing doses, up to one hundred grains, three times a day. He gained flesh and improved up to a certain point, but afterward became worse. No convulsions had occurred for some time before he left the hospital.

A RARE CASE OF PAINLESS DISTENTION AND PROLAPSE OF THE BLADDER TWO MONTHS AFTER CONFINEMENT.

By S. J. RADCLIFFE, M.D.,
of Washington, D. C.

Without excuse for its delay, though late, I think the following unique case worthy of record. It is one of those accidental occurrences sometimes met with in practice, often quite unexpectedly, which puzzles and puts one to his wits' end for solution. On the promptness to recognize and to relieve in such cases depends always the welfare of the patient. Failure to recognize or correctly diagnose, at a sudden summons, in these emergencies might often result disastrously or even fatally.

Mrs. A., aged thirty-five years, mother of two children, in good health, was confined with her third child, Sept. 17, 1886. She had a quick, natural labor, and the child was delivered without difficulty. She convalesced rapidly, and after the usual period I left her in her ordinary health.

November 12th, following, about two months after confinement, on a pleasant fall day, in company with her husband, she walked, pushing her babe before her in a little child's carriage, some ten or eleven squares, about three-fourths of a mile, to pay a visit to a relative. On her arrival at her place of destination she was taken suddenly ill, and I had an urgent call to see her.

On my arrival I found her in an almost collapsed state. Her countenance was pale, her surface cold, her pulse small and quick, the whole body agitated as if with a chill, and she seemed to be suffering from profound shock.

She could scarcely describe her feelings or symptoms, but referred her ailment to the lower part of her abdomen. On placing my hand upon the abdomen, however lightly, she could not bear the touch on account of the pain it produced. The entire abdomen, at least to the umbilicus, was equally tender and admitted of no manipulation. I questioned her in regard to the condition of her bowels, uterus, and bladder, but elicited nothing definite. She replied as well as she could that she had been careful of herself, and had had proper attention, and she had felt no inconvenience or discomfort until now. She thought she had had a passage from the bowels, and also passed her urine that morning, but was not certain, and so far as she knew she had had no uterine trouble since her confinement.

I suggested that the only rational way to determine the cause of her illness, which was important as the symptoms were more or less uncertain, was to make an examination per vaginam, to which she willingly consented.

On attempting to introduce my finger into the vagina, the patient being on her back, it came at once in contact with a round, tense, smooth projection or tumor, slightly elastic and of uniform outline, completely filling the mouth of the vagina to the vulva, by separation of which it could be easily seen. I was not certain at first whether it was the walls of the vagina in a prolapsed state dragging

some organ with it, as the uterus, or the uterus itself, in a condition of prolapse pressing down upon it; an abscess, or hæmotocele, or other extravasation, or even a hernia of the bowels. I could pass my finger only at the posterior aspect by pressing down the perineum, and by keeping my finger in that position and gently pressing upon the abdomen in a wave-like motion; above the symphysis pubis I found the impulse communicated to the tumor, and my finger, and after several trials I concluded it must be cystic, probably a distended and prolapsed bladder due to dysuria from partial or complete paralysis of either the bladder or sphincter vesicæ, or both.

There was no dribbling, or any evidence of the passage of urine and the urethral orifice was intact. The parts contiguous to the meatus were not swollen or painful to the touch, and there was no evidence of diseased structure anywhere discovered by the closest inspection.

I at once introduced a long, soft elastic catheter into the bladder, and the diagnosis was verified directly by the passage of a full stream of urine, and I drew off two-thirds of a large china basinful of dark, amber-colored urine, probably two quarts or sixty-four ounces, free from bad odor, and appearing to be of recent accumulation. After the discharge the tumor subsided completely, admitting my index finger freely into the vagina, and permitting an examination in any direction, which revealed no other displacement, and showed only a dilated condition of the anterior wall of the vagina.

The most pressing symptoms now disappeared, warmth returned to the body, the pulse increased in strength and volume, she could bear more readily pressure upon the abdomen, and in a short time she was free from pain or distress. I enjoined her to keep quiet; gave her some quieting medicine, containing morphia and potassium bromide in camphor water, and left her quite comfortable.

I saw her again the same evening, and as she had not voided her urine, I introduced the catheter and evacuated about two ounces.

She had not perfect control over her bladder for something like a week after her attack, and I was obliged to repeat the catheterism each day for the first few days twice daily, and after that once daily, and when I discontinued my visits I left the catheter with her, as she had learned to use it herself, and I directed her if she felt any lengthy continuance or retention of urine to use it or send for me. She had no further trouble, however, or necessity for its use, and seemed to recover from the affection completely.

The points of interest presented in this case are: the painless and apparently sudden distention of the bladder, almost to the stage of rupture, without giving distinctive warning of such a condition; the great and persistent shock to the general system it produced, and the relation existing, if any, to the recent confinement of the patient.

It is a matter of great surprise or wonder that in the midst of apparent good health, at least without any show of depreciated vitality, and in a sound condition of the organ itself, the bladder could have so filled, possibly by gradual additions, or it may have been by rapid secretion, until it had measured its utmost capacity, even to the verge of rupture, without giving sooner some decided evidence of its impending danger.

At the birth of the child there was no delay in the passage of the head through the lower strait, and consequently no great amount of pressure upon the neck of the bladder, or injury to the soft parts along its course. There was nothing during her lying-in or getting-up indicating any disturbance of its function. She thought she had attended to herself and to its evacuation daily, and felt no unpleasant symptoms or discomfort in doing so. The first ill feeling she had of any kind was the sudden shock she felt after her long walk, but which she did not refer particularly to the bladder. She said she then had an indescribable feeling of exhaustion, sinking or fainting and would have fallen if she had not been supported.

There was no stricture of the urethra or prolapse of the uterus, and no other pressure to obstruct the flow of urine.

It is possible that inattention or negligence of her duty to herself that morning, with the long, fatiguing walk, and a somewhat relaxed condition of the system, and probably also, in addition to the fatigue, an overheated state of the body, constituted some of the factors in the case, or at least were some of the exciting, if not the remote, causes of the trouble.

Excessive exercise, we know, increases the secretion of urine by the kidneys. This is a physiological fact, demonstrated by frequent experiments. Disassimilation is then more active, and consequently a greater effort is made to get rid of the effete, azotized matters which the blood takes up during the process of disintegration. This is, of course, governed in a great measure by the state of the circulation, the amount of blood-pressure, the condition of the nervous system, and the amount of transpiration, and also by the quantity of fluid taken.

The true pathological condition was an over-distended bladder, producing paralysis by distention, and inability to contract on itself or its contents; but what brought about this condition it is difficult to determine, however much one may surmise.

The shock was no doubt caused by or due to the generally lowered or depressed vitality at the time, it may be to the fatigue of the patient, and to the immediate disturbance or impairment of a vital function—the impression being made through the sympathetic system, or by reflex action, and involuntary in its nature; familiar examples of such reflexes are often presented, as in the often repeated one of simply introducing a catheter. The relation of the recent confinement to the case could hardly

be considered important, as its remoteness, and doubtless complete recovery from that state would possibly preclude consideration. A very important item to be considered in the case was the diagnosis. Any delay or failure in recognizing the state of the patient would have resulted in rupture of the bladder. In her complicated condition this was a very nice point, and called for prompt action.

1523 K STREET, N. W.

MEDICAL PROGRESS.

Antipyrin in Hay Fever.—DR. ADOLPHE BLOCH, formerly physician to the Havre Hospital, has used antipyrin with excellent results in a case of spasmodic rhinitis (hay fever). The patient was a man aged thirty-three, who complained of cold in the head, from which he had suffered for two years. The affection manifested itself, in the morning on rising, and in the afternoon when the window was opened, by painful attacks of sneezing, with a copious discharge of watery mucus. There was severe itching and pricking in the eyes, which watered incessantly; and pain in the head over the frontal sinuses. These symptoms completely disappeared during the intervals between the attacks. The throat and the nasal fossæ were normal. On July 6, 1887, 30 grains of bromide of potassium were prescribed; these were administered daily, morning and night, in syrup of orange-peel. From July 18th one pill, containing ¼ of a grain of extract of belladonna, was given every morning. The interior of the nose was constantly painted with a solution of hydrochlorate of cocaine (one to thirty parts of water). This treatment was continued for a week. The affection disappeared for two days, but subsequently reappeared. The dose of extract of belladonna was then administered twice daily. Ten days later, finding this treatment did not produce satisfactory results, M. Bloch ordered 30 grains of antipyrin daily at the hours at which the attacks usually came on. After the first dose the affection ceased. During eight days only two slight attacks occurred. The treatment was discontinued for six days, during which there were no attacks; it was then resumed. During twenty days only two slight attacks occurred; 15 grains of antipyrin were then administered daily before breakfast. The treatment was discontinued from September 20th to October 3d. On November 8th the patient stated that the hay fever had disappeared since the early part of October, although he had ceased to take antipyrin. M. Bloch considers that the anæsthetic action of this substance was not confined to the sensory and secreting nerves of the nasal fossæ; it is highly probable that the special action of the antipyrin on the encephalic nerve centres caused the hyperæsthesia of the Schneiderian mucous membrane to disappear.—*British Medical Journal*, January 7, 1888.

The Value of Salol.—The *British Medical Journal* of December 24, 1887 writes as follows regarding the value of salol:

According to the most recent observations the principal effect of the administration of salol is to produce a marked and immediate remission of the pain in cases of acute rheumatism. Its effect on the temperature, however, is less marked than that obtained by means of the salicylate of sodium, and the relief afforded is of much shorter duration. In fact, unless the patient is kept well under the influence of the drug the suffering returns in its original intensity. Salol is, to all its intents and purposes, innocuous, and is said never to give rise to toxic symptoms. Even the discomfort which not infrequently follows the internal administration of salicylate of sodium has not been observed with salol. Hence, whenever the use of the former drug is contraindicated, salol will be found both useful and reliable. The best effects were obtained with it in the treatment of subacute rheumatism, and the patients soon learn to appreciate the relief which follows its administration. Salol is insoluble in pure water, but is slightly soluble in organic liquids of alkaline reaction. It is best given in the form of compressed tablets, pills, or in an emulsion.

Salol, for External Application.—Salol collodion;

Salol	ʒ 1.
Etheris	ʒ 1.

add

Collodion. flex.	ʒ 7½.

Especially useful for excoriated nipples.

A salol ointment for burns:

Ol. oliv.	ʒ 15.
Salol	ʒ 2½.
Aq. calc.	ʒ 15.

—*Centralblatt für die Gesammte Therapie*, January, 1888.

Ovaroclasia.—From *Gazetta degli Ospitali*, No. 70, 1887, we learn that PORRO has devised an operation in which he crushes or destroys ovarian tissue in cases where the removal of the ovary is contraindicated. It has been successful in several cases.

Paraplegia from Disease of the Urinary Organs.—ETIENNE concludes his study of this subject as follows, in the *Revue Gén. de Clinique et de Ther.* of December 22, 1887:

In the course of an acute affection of the urinary organs disturbances of motion and sensation in the lower extremities may occur at any time. Such cases are rare; and in the great number of cases the lesions of the urinary organs are not a cause but a consequence of nervous disease. These cases occur most frequently in the neurotic.

Two Successful Extirpations of the Larynx.—DEMONS, of Bordeaux, reported at a meeting of the Paris Academy of Medicine on December 20, 1887, two cases of extirpation of the larynx for cancer. The first, a partial exsection, was performed in May, 1887, and the second in June, 1887. Up to the date of meeting the patients were without inconvenience and in good health. They were not using artificial larynxes.—*L'Abeille Médicale*, December 26, 1887.

Salt in Milk for Children.—JACOBI, in the *Archives of Pediatrics* for January, 1888, writes that the physiological

effect of chloride of sodium is very important, no matter whether it is directly introduced through the mother's milk, or added as a condiment to cow's milk, or vegetable diet. Both of the latter contain more potassium than sodium, and neither ought ever to be given, to the well or sick, without the addition of table salt. A portion of that which is introduced may be absorbed in solution; another part is, however, broken up into another sodium salt and hydrochloric acid. Thus it serves directly as an excitant to the secretion of the glands and facilitates digestion. Therefore during diseases in which the secretion of gastric juice is interfered with, or in the beginning of convalescence, when both the secreting faculties and the muscular power of the stomach are wanting, and the necessity of resorting to nitrogenous food is apparent, an ample supply of salt ought to be furnished. The excess of acid which may get into the intestinal canal unites with the sodium of the bile in the duodenum, and assists in producing a second combination of chloride of sodium, which again is dissolved in the intestines and absorbed. Its action in the circulation is well understood: it enhances the vital processes, mainly by accelerating tissue-changes through the elimination of more urea and carbonic acid.

A very important fact is also this: that the addition of chloride of sodium prevents the solid coagulation of milk by either rennet or gastric juice. Thus cow's milk ought never to be given without table salt, and the latter ought to be added to woman's milk when it behaves like cow's milk in regard to solid curdling and consequent indigestibility.

Habitual constipation of children is also influenced beneficially, for two reasons: not only is the food made more digestible, but the secretions of the alimentary canal, both serous and glandular, are made more effective by its presence.

The Isolation of School Children Suffering from Contagious Diseases.—Ollivier, in *Gazette Heb.* of December 30, 1887, advises that children suffering from variola, scarlatina, and diphtheria be isolated for forty days; those suffering from varicella and measles for twenty-five days. He advises two full baths with soap for each convalescent, and the thorough disinfection of clothes and rooms; children should not be admitted to schools without clean health records, signed by physicians.

Obstetric Cones.—Since the local anæsthetic properties of cocaine have been discovered, among the many purposes for which it has been applied is that of relieving the earlier labor pains by painting with it the os uteri in primiparæ, or when the os is rigid; but in order to do this adequately, the use of a speculum is necessary. The obstetric cones recently made do away with this difficulty. They are hollow, made to fit the index finger, and can thus be very readily applied to the part desired. They are made with one, two, or three grains of cocaine, the excipient being oil of theobroma, and they also contain three grains of boric acid. The excipient itself acts as a lubricator to the parts. Therapeutically they fulfil their purpose very well, and from a pharmaceutical point of view they seem to be incapable of further improvement.—*British Medical Journal*, January 7, 1888.

Digital Divulsion of the Pylorus.—From *Gazzetta Degli Ospitali* of December 25, 1887, we learn that Brichetti has recently performed digital divulsion of the pylorus for stenosis of extreme degree. The operation lasted about forty-five minutes. The stomach was closed by Lembert sutures, and the abdomen was sutured by deep and superficial stitches. Strict antisepsis was observed, and when the report was made, twenty-four hours after the operation, the patient's condition was good.

A Prescription for Asthma.—Professor Beaumetz prescribes:

Potass. iodid.	ʒ 3¾.
Tinct. lobeliæ	ʒ 3¾.
Aquæ destil.	ʒ 7¾.

M. S.

A teaspoonful or tablespoonful may be taken, in a glass of beer, at meals.—*Journal de Méd.*, December 25, 1887.

Sulphide of Carbon in Elephantiasis.—In the *British Medical Journal* of December 24, 1887, appears a letter by Dr. P. D. Anthonisz, of Ceylon, giving the results of the use of sulphide of carbon in elephantiasis, both acute and chronic, as tried by himself and a few of his medical friends. In some of the acute cases, the reduction of swelling was prompt and complete, in others it was gradual but satisfactory. In one, a case of thirty years' standing, a year's treatment, begun when the legs were as large as the man's waist, left them about the size of his thighs. The dose mentioned in the latter was two two-grain pills per diem, to be continued for a lengthened period, except when the drug irritates the stomach, as it will do from time to time. When the ill effects have passed, the medicine should be renewed. The writer adopts the theory proposed by Dr. Manson, of Amoy, some years ago, that the disease is due to the presence, in the blood, of the *filaria sanguinis hominis*. He believes that the remedy is efficient by reason of its sulphur ingredient and its power to prevent the parasite from multiplying in the body; which, according to Dr. Manson, it does with amazing rapidity. It will be remembered, that in accounting for the presence of the filaria in the blood, the theory of Dr. Manson included the novel proposition that the mosquito might carry in the parasite with his proboscis, and deposit it in tissues whence access to the blood could readily be obtained.

A Needle Ten Months in the Larynx.—Vámossy reports the case of a tailor who consulted him in December, 1886, for relief from a needle and thread which he had swallowed while at his work. Examination of the larynx showed a dark body on the edge of the left vocal cord, which was removed by forceps, and proved to be a bit of black thread. The irritation and cough were relieved, and the patient dismissed.

The physician heard nothing from the patient until November, 1887, when he returned, bringing a rusted needle, about one inch long, without an eye, which he had coughed up a few hours before. The reporter considers it probable that the needle had been retained in one of the ventricles of Morgagni.—*Wiener med. Presse*, No. 52, 1887.

Resorcin in Laryngeal Tuberculosis.—Dr. M. A. Fronstein, of Moscow, writing in the *Russkaya Meditsina*, on

resorcin in laryngeal tuberculosis, states that he has found that this substance, though not so powerful a local anæsthetic as cocaine, acts more satisfactorily in allaying the pain and distress caused by laryngeal ulceration of tuberculous origin. In out-patient practice he applies a 10 per cent. solution, and if after a minute or so the pain is not decreased, he repeats the application, using a 20 per cent. solution. He then gives the patient a supply of this latter solution and a brush, and teaches him to apply it himself, the situation of the most painful spot being his guide. As a rule, patients can manage the application pretty well, as the ulceration is usually situated on the arytenoids or on the edge of the epiglottis, localities tolerably easy of access. Where possible, of course, the operation should be performed by a medical man with the aid of the laryngoscope. In addition to these direct applications, a spray containing 2 per cent. of resorcin is used several times a day. Under this treatment considerable improvement was usually manifest, and sometimes, when cocaine was substituted for resorcin, the patient would beg that the first remedy might be given him again, as the change had not suited him. Another advantage resorcin has over cocaine is its comparative cheapness, the price being only about 1*s.* per ounce, whereas the hydrochlorate of cocaine is still 5*s.* a drachm.—*Lancet*, January 7, 1888.

The Doses of the Alkaloids.—At a recent meeting of the Paris Pharmaceutical Society, BENOIT urged that uniform preparations of strophanthin, digitalin, and aconitin be employed, and that the scale of dosage be upon $\frac{1}{5}$th of a milligramme (about $\frac{1}{600}$th of a grain). He proposed the following formulæ:

For digitalin—

Digitalin	gr. ⅙.
Sacchar. lact.	ʒ i.
Acaciæ pulv.	grs. 15.
Syrup. acac.	q. s.

To be made into 100 granules.

Aconitin may be prepared as follows:

Aconitin. nitrat.	gr. ⅜.
Sacchar. lact.	ʒ i.
Gumm. acac.	grs. 15.
Syrup. acac.	q. s.

Which may be made into 100 granules.

It is suggested to color granules of substances especially dangerous.

(The dose of aconitine is different, according to these formulæ, from that of digitalin.)—*Journal de Méd.*, December 25, 1887.

The Prevention of Ophthalmia Neonatorum.—In a Prize Essay, published in the *Manchester Chronicle* for January, 1888, MULES advises the following measures for preventing ophthalmia neonatorum:

(1) Cure of all cases of chronic vaginal discharge before labor by suitable local applications.

(2) Irrigation of the vagina during the second stage of labor when vaginitis is known to exist. The plan, adopted in London, at Queen Charlotte's Hospital, is almost uniformly successful. The solution in use is hydrarg. corros. sublim., 1 part to 2000. Nature has herself indicated this method by copiously secreting a clear vaginal fluid before and during labor, and the rush of liquor amnii immediately preceding birth; the action of these fluids is more than mechanical, for experiment proves that a freely diluted blennorrhœal secretion is non-infectious, although, to be with certainty innocuous, it should not be more than 1 per cent.

(3) By assisting the fœtal eyes to pass beyond the perineal edge without resting. This is easily done by hooking the finger round the perineal edge and drawing it down.

(4) By wiping the eyes with a clean cloth at birth of head.

(5) By instilling an antiseptic solution into the child's eyes at birth, *if the mother is known to have vaginal discharge*. To do this in all cases is unnecessary. Credé's method—solution used, argent. nit. 2 per cent.

(6) To wash the face first, never in the water in which the body has been cleansed.

(7) To retain one sponge or flannel specially for the child's face, and to insist on scrupulous cleanliness.

(8) The nurse to wash her hands after adjusting the mother, before touching the child.

(9) Not to expose unduly the child to bright light, draughts, etc.

(10) To protect the child from flies, with a thin veil.

(11) To remove carefully the child from the immediate vicinity of another similarly attacked. (General isolation.) I cannot too forcibly reiterate that "ophthalmia neonatorum" is an infectious disease, and all medical officers or superintendents of crèches, workhouse schools, or hospitals, should treat it as such, and remove the infected child to an isolation ward at once.

(12) To guard the one eye if the other is affected. (Special isolation.) This is very difficult in infants, and depends entirely on the care and intelligence of the nurse, the constant removal of discharge, and the general watchfulness which cannot be defined.

Creasote in Phthisis.—HOFMANN, in the *Berliner klinische Wochenschrift*, No. 52, 1887, reports that he has prescribed creasote in liquid form, *well diluted*, advising a half or a whole wineglass of water to be taken with the dose. He believes that patients bear the liquid form of administration better than the solid, as less gastric irritation ensues. He has combined creasote, gtt. ¾, with balsam of tolu, in capsules, with advantage.

Penetrating Gunshot Wounds of the Chest.—DR. GOUZIER has published some observations and statistics regarding the penetrating gunshot wounds of the chest occurring in the French expeditions to Formosa and Tonquin in 1883–85. From his work we gather that such wounds showed a mortality of 10 per cent., which is only about a sixth of that due to similar wounds in recent European wars and in the American war. Apparently, as he suggests, the general employment of antiseptic methods was the cause of this great amelioration. Chest wounds from revolver balls of seven millimetres in diameter generally proved comparatively harmless. Traumatic pleurisy and pneumonia usually terminated favorably, but hemorrhage, empyema, and compound fracture of the ribs gave much more serious results. He found that the best practice was not to explore unless it was necessary to extract the ball, and not to attempt extraction unless the ball was just beneath the skin or was setting up dangerous complications. In ordinary cases he found the best plan was

to close the wound antiseptically; but if there was empyema, to make a counter-opening and to wash out and drain the pleural cavity. Warm antiseptic baths were also found very useful in Tonquin.—*Lancet*, January 7, 1888.

The Treatment of Bleeding Hemorrhoids.—BUCHHOLTZ prescribes:

Alum. pulv.	grs. 45.
Ext. rhatan.	grs. 45.
Conserv. rosar.	grs. 90.
Catechu pulv.	grs. 90.
Syrupi	q. s.

M.—Ft. pil. 60 in num.—Sig.

Two pills at night and morning.—*Les Nouveaux Remèdes*, December 24, 1887.

Tribromphenol, an Antiseptic.—In the *Deutsche medicinische Wochenschrift* of December 29, 1887, GRINEM reports his experience with this substance as follows: It is a combination of bromine with phenol, and is a white, crystalline powder, very insoluble in water, easily soluble in alcohol, ether, chloroform, and other similar liquids. It is but little dissolved by glycerine, carbolized solutions, and dilute spirits of wine.

It is dissolved by the intestinal secretions, combines with sulphuric acid, and appears in the urine as a sulphuric compound. It is not escharotic, but powerfully stimulant to granulations; it does not attack the unbroken skin.

It was used in gauze dipped in 2½ per cent. solution, with good results, in tamponing wounds and cavities; it is well adapted as a stimulating tampon for abscess cavities, but should not be used in the pharynx, mouth, or nares.

In experiments upon bacterial cultures a 1 per cent. solution sterilized septic matter in thirty minutes; in 3 to 1000 solution it sterilized gelatine cultures. A small quantity added to urine prevented decomposition. The writer gave this substance in three doses of 1½ grains each, to a patient suffering from tænia, with good results; the whole was given within an hour and a half. Personally, he took as much as 15 grains in twenty-four hours; the only effect being a slightly uncomfortable feeling in the abdomen, and an unpleasant taste.

The use of this substance seems indicated to stimulate granulations; and, by virtue of its insolubility in acids and its solution in alkalies, as an intestinal antiseptic.

Resorcin in Cancer.—The *British Medical Journal*, states that resorcin has been used with excellent results in the treatment of cancerous growths on the face, in the form of an ointment containing equal quantities of resorcin and vaseline. This mixture is applied first; an ointment containing 20 parts of resorcin to 30 parts of vaseline is then applied. The ointment forms eschars on the surface of the growth. These eschars fall off when pure or iodoform vaseline is applied; fleshy granulations subsequently appear, and healthy cicatrization rapidly follows.

Saccharin in Emulsions.—The *American Druggist* for January, 1888, gives the following formulæ for emulsions, with saccharin:

The flavoring and preservation of emulsions ought not to be overlooked. Although an emulsion may be therapeutically and mechanically perfect, it is often nauseating to the taste and offensive in odor. Flavoring, though only an adjunct, still does contribute elements of value to a medicine. The common favorites among flavors are those used in cookery, such as the volatile oils of almond, cinnamon, cassia, cloves, lemon, the essence of vanilla, and orange-flower water. My opinion of these as regards permanency, palatability, and power to disguise is in favor of almonds. An elegant cod-liver oil emulsion is made as follows: (The weights and measures are British.)

Cod-liver oil	4 ounces.
Powdered gum acacia	1 ounce.
Oil of cassia	4 minims.
Oil of almonds (volatile)	4 minims.
Saccharin	2 grains.
Water to make	8 ounces.

Mix the oils with the gum and saccharin in a dry mortar, add 2 oz. of water, stir till the emulsion is formed, finally, add sufficient water to make 8 oz., then mix well.

Castor-oil is well disguised in the following formula:

Castor oil	1 ounce.
Powdered gum acacia	3 drachms.
Oil of almonds (volatile)	2 minims.
Oil of cloves (volatile)	1 minim.
Saccharin	1 grain.
Water to make	4 ounces.

Mix the oils with the gum and saccharin in a dry mortar, add 4 drachms of water at once, stirring till the emulsion is formed, dilute to 4 oz. with water.

Having saccharin at our disposal provides us with a useful substitute for sugar in emulsions. Its advantages are that it adds nothing to the thickness of the product, and cannot give rise to fermentation. The method found most convenient for using saccharin is a 10 per cent. solution made by adding bicarbonate of sodium till effervescence ceases; 20 grains of saccharin take 8 grains of the soda salt.

To keep emulsions for long periods is not desirable; they are best freshly made. Should it be desired to preserve them, recourse must be had to such antiseptics as boric or salicylic acid, or, better, perhaps, a simple tincture of benzoin, or even pure chloroform. The latter is a most powerful antiseptic, imparting an agreeable sweetness; 1 minim may be added to each ounce of emulsion.

Hyoscin may be conveniently administered in

Hyoscin. hydrobrom.	gr. ⅙ to ⅓.
Aq. destill.	ʒ 17½.
Syrup. aurant. cortic.	ʒ 7½.—M.

Sig.—Dose one teaspoonful.

—*Deutsche med. Wochenschrift*, January 5, 1888.

The Care of the First Teeth.—MILLER, of Berlin, writes as follows in the *Therapeutische Monatshefte* for January, 1888:

The influence of the first teeth upon the general health of the child is as great as that of the second teeth.

The care of the first teeth should begin very early, and consists in careful cleansing, the avoidance of injurious substances, and prompt filling of cavities.

Dental operations on children should be carefully estimated in proportion to the strength of the patient, and pain should be as carefully prevented as possible. Affections of the periosteum and bones of the jaws are quite susceptible of treatment in children. The conservative treatment of the first teeth, when once decayed, is more difficult than that of older teeth. Caries of the first teeth has an unfavorable influence on the later teeth; first teeth, when diseased extensively, should be promptly removed. The extraction of the first canines should not be done too rapidly, otherwise the second teeth may be irregularly placed.

Penetrating Wounds of the Stomach and Meso-colon: Laparotomy; Cure.—At a recent meeting of the Surgical Section of the Royal Academy of Ireland, MR. BALL brought forward the case of a boy, aged fifteen, who was admitted into Sir Patrick Dun's Hospital on March 29, 1887, immediately after having accidentally stabbed himself with a half-inch chisel. The blade perforated his abdomen about half way between the tip of the ensiform cartilage and the umbilicus, and about a quarter of an inch to the right side of the linea alba. Dr. Ball saw him four hours after the injury; he was then profoundly collapsed; he vomited blood at frequent intervals, and at each effort to vomit a stream of blood spurted out from the abdominal wound. The whole abdomen was dull on percussion. An incision about three inches long was made in the middle line, between the ensiform cartilage and the umbilicus, and the chisel wound connected with it. As soon as the peritoneum was opened, a considerable quantity of blood gushed out. The stomach was found to be wounded. A clean cut existed in the great curvature, about half an inch in length; it was not bleeding. The mucous membrane, though perforated, was not prolapsed, and none of the contents of the stomach were found extravasated. The wound was sutured by passing a fine catgut suture, after the method of Lembert (but continuous), four times across the wound, only including the serous membrane; the ends were then tightly tied, thus absolutely closing the opening, and at the same time puckering up the serous membrane and bringing a considerable area on each side of the wound into apposition. The omentum was reflected upward and search made for other wounds, as copious bleeding continued. An opening in the transverse meso-colon, near its spinal attachment, could be felt with the finger; and, upon sponging away the blood, it was found that a large vein was wounded, to which, with some little difficulty, a catgut ligature was applied. The patient vomited shortly after the operation, but the vomit was free from blood. He was allowed nothing by the mouth, except small pieces of ice, for six days, and was fed by nutrient enemata of artificially digested food. From the sixth to the fourteenth day, he was allowed gradually increasing quantities of beef-tea and milk, and he then was allowed solid food. On the third day, he vomited some pieces of onion, quite unchanged, which, he stated, he had eaten the morning of the accident. Four weeks after the operation, he was discharged from the hospital quite well.—*British Medical Journal*, January 14, 1888.

Strychnia in Alcoholism. — The good results obtained from strychnine in dipsomania by N. M. Popoff, V. A. Manasseïn, Partzevsky, Tolvinsky, and Zavadsky, have induced DR. S. JAROSHEVSKY (*Meditzinskoïe Obozremiè*, No. 4, 1887, p. 332) to undertake an experimental inquiry into the antagonism between the alkaloid and alcohol. From experiments made on dogs Dr. Jaroshevsky feels justified in drawing the following conclusions: 1. Strychnine undoubtedly neutralizes the intoxicating and narcotic effects of alcohol. 2. It enables large quantities of alcohol to be taken for a considerable stretch of time without causing the usual organic lesions which follow the use of alcohol alone. 3. There are, however, limits beyond which the alkaloid itself becomes injurious to the organism. 4. Therapeutically, strychnine should be used in all forms of alcoholism. 5. It may be regarded as a powerful prophylactic against alcoholism.—*British Medical Journal*, January 14, 1888.

The Administration of Sparteine.—DEBIERRE prescribes sparteine as follows:

Aquæ	℥ 11¼.
Aquæ lauro-cerasi	℥ 3¾.
Syrup. simpl.	℥ 5.
Spartein. sulph.	grs. 4½.

A teaspoonful morning and night.

In pill form sparteine may be given in

Spartein. sulph.	grs. 8.
Mass. pilul.	q. s.

M.—Ft. pil. 10 in number.

Two to four pills may be given during twenty-four hours.—*Les Nouveaux Remèdes*, December 24, 1887.

Permanent Catheterization and Forced Feeding in Œsophageal Stricture.—At a recent meeting of the Berlin Medical Society LEYDEN exhibited two patients whom he had nourished by introducing a canula as large as a goose quill into an œsophagus contracted by cancer, through which forced feeding was carried on. Attached to the canulæ were threads of silk, which were fastened over the ears, and prevented the canula from going into the stomach.—*Therapeutische Monatshefte*, January, 1888.

The Prophylaxis of Diphtheria.—JOHANNSEN, of Libau, has used with excellent results a clear, red solution of potassium permanganate as a gargle. Believing that bacteria taken into the throat during the day are very likely to multiply during the night the gargle is used before retiring. He is convinced that the procedure is rational and efficient.—*St. Petersburg Med. Wochenschrift*, No. 37, 1887.

The Antiseptic Action of Biniodide of Mercury and Potassium Iodide.—KRASSOWSKI, of St. Petersburg, reports a series of eleven laparotomies in which he used as an antiseptic equal parts of biniodide of mercury and potassium iodide in solution. Two deaths occurred, from causes not connected with the operation; in each case post-mortem examination showed union of the wound by first intention, and absence of septic inflammation. The mercurial was first used in a strength of 1 to 1000, which was progressively diminished to 1 to 4000.

Krassowski concludes that a solution of 1 to 4000 is an efficient antiseptic, and that this substance is less irritant than the bichloride, and can be applied to the integument in five per cent. solution, without producing irritation.—*Gazette de Gynécologie*, January 1, 1888.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,

Per Annum, in Advance . . . . . $5.00.
Single Copies . . . . . 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia.

SATURDAY, FEBRUARY 4, 1888.

HIGH RECTECTOMY FOR CARCINOMA.

When carcinoma of the rectum is seated too high to be reached from below by the ordinary procedure, and too deep to be excised through the belly, the operation of Kraske, of Freiburg, described in the *Verhandlungen der Deutschen Gesellschaft für Chirurgie*, Bd. ii. 1855, affords the quickest and safest measure to expose and remove it, along with the perirectal tissues, should they be implicated through local extension of the disease.

The procedure, it will be remembered, consists, briefly, in making a median cut from the second sacral vertebra to the anus; severing the left gluteus maximus muscle from its attachment to the sacrum; excising the coccyx; detaching the sacral connections of the tuberososacral and spinososacral ligaments; and chiselling away the lateral mass of the sacrum in a curved line, which begins at the outer border of the third sacral foramen, and terminates at the cornu of the sacrum. The anus being now freed by a circular incision, the rectum is detached from its bed; the peritoneal cavity is opened, also, by a circular cut; the gut drawn well down and amputated above the tumor, and its end fixed by sutures to the paraänal tissues. The operation is completed by inserting a drainage tube into the peritoneal cavity, and plugging the rectum and wound with iodoform gauze.

In his first case, the disease recurred at the expiration of four months. In 7 subsequent cases in the hands of Kraske, in 3 from the practice of Schönborn, in 1 from that of Rinne, and in 1 from that of Lauenstein, the anus and lower portion of the rectum were spared, and about two-thirds of the anterior wall of the central end of the gut were united by sutures to the peripheral end, the posterior segment of the tube being left open for the escape of the feces. Of these 12 cases, 5 died, 2 of exhaustion, 1 of sepsis, 1 of peritonitis from giving way of the stitches and the entrance of fecal matter into the cavity of the belly, and 1 of iodoform intoxication. Of the 7 recoveries, 3 had fistulous openings at the expiration, respectively, of three, three and a half, and five months; in 2 the healing process was not completed until the end, respectively, of six and eleven months, from the formation of a sacral artificial anus; and 2 were recorded at the end, respectively, of one month and three months. Hence of the entire number, 38 per cent. perished, and, so far as we are aware, not a single one was permanently cured.

Although the operation of Kraske is better than the old procedure, it is open to the serious objections that the peritoneal cavity is not closed, and that the contact of fecal matter with the wound prolongs the healing process, and favors septic complications and the formation of a sacral artificial anus.

To overcome these disadvantages, Schede, in a paper read last September before the Medical Society of Hamburg, and published in the *Deutsche medicinische Wochenschrift*, No. 48, 1887, describes three cases in which, after doing the preliminary steps instituted by Kraske, he introduced certain modifications. In the first case, he attached the divided peritoneum to the serous surface of the sigmoid flexure of the colon, thereby closing the cavity of the belly, and left the anus, sphincters, and lower end of the gut intact, and secured it to the central end with two circular rows of sutures, of which the first included the mucous membrane, and the second the other coats of the bowel. The wound was dressed with iodoform gauze, and opium administered to control the stools. The result was not wholly satisfactory; the ends of the gut did not entirely unite by primary intention, and nearly a year elapsed before the complete closure of the small fistulous track. The sphincters retained their functions, however, and there was no difficulty from involuntary evacuations.

The great value of closing the peritoneal cavity is shown by two cases recorded by Kraske, in which

that feature of the operation was omitted, although complete reunion of the divided ends of the bowel was attempted. In both instances the stitches gave way, during a stool, which occurred a few hours after the operation, despite previous care to empty thoroughly the lower bowel, and the subsequent exhibition of opium, and death ensued from peritonitis from fecal extravasation.

The protracted healing in the case of Schede was due to contact of feces with the sutured bowel. Hence, in the other two operations, to obviate this complication, immediately after resecting the rectum, he made an artificial anus between the belly and descending colon. In the first of these, four-fifths of the rectal wound united by the first intention, and the remainder by granulation, while the outer wound had closed in two months and a half. The artificial opening was then remedied, and at the end of four months from the primary operation the patient was discharged. The second of these cases pursued a very similar course.

The modifications practised by Schede are certainly very great additions to the original procedure. Considered together, the two operations have been performed at least 18 times, with 7 deaths, which is a high rate of mortality, and only a slightly better showing than the ordinary operation for high carcinoma affords. Thus, of 10 cases of Bardenheuer's procedure in the hands of Kümmell, 2 died shortly after the operation, 2 died of sepsis, and the disease recurred in the remainder at intervals which ranged between five and twenty-four months. Bardenheuer's method, it may be stated, consists in removing the anus, sphincter, bowel, and tumor, opening the peritoneal sac, and drawing down the divided gut, and attaching it to the perianal tissues.

It will be observed that the operation of Kraske, or its modifications, has been done solely by German surgeons, so that we infer that excision of high carcinoma of the rectum is not regarded favorably by the profession at large. If this be true, we think that the attitude assumed by surgeons of other parts of the world is most commendable, and that they should not practise the operation until their bolder confrères show that it affords a fair percentage of permanent recoveries. Until this be done, we have no hesitation in saying that the best procedure in this class of cases is left lumbar colotomy as modified by Madelung, of Rostock. The colon having been divided, its central end is united to the lumbar wound, and its lower end is dropped, after closure of its lumen. By thus preventing the contact of fecal matter with the growth, discomfort and pain are effectually checked though the withdrawal of the source of mechanical, chemical, and septic irritation.

IDIOPATHIC DROPSY.

ANY physician in large practice has probably seen cases of dropsy in which it has been impossible to assign a satisfactory cause for the effusion, in the absence of heart, renal, or blood disease. The older writers had a good deal to say about this essential dropsy, but naturally with the increased facilities for diagnosis the number of cases has been reduced to a minimum, and so little regard has been of late paid to it, that even the name does not appear in the ordinary nomenclatures of disease.

In the last number of the *Deutsches Archiv für klin. Medicin*, WAGNER, the well-known Leipsic pathologist and clinician, has an exceedingly suggestive article, giving his experience with this form of dropsy, which in its distribution and general appearances resembles most closely that of renal disease. He gives first a report of six cases in children, in all of whom the dropsy was general, most intense, as a rule, in the legs, and not of great extent in the serous sacs. In all there was pallor, but not anæmia of such a grade as could possibly induce the general œdema. There was no fever, but the cases gave the impression of a serious illness, and three of the six children died. The most careful examination failed to reveal any heart, kidney, or serious blood changes, and in the three fatal cases the anatomical condition threw no light on the cause of the dropsy.

Two cases are mentioned in young bakers, apprentices at the age of fifteen, much exposed to changes in temperature; five cases in adults are referred to, all following cold, and two cases are given in full. With the exception of the last case, none of these presented any of the changes usually associated with anasarca. Case VII. we should certainly not class with the others, as it seems an instance of œdema from anæmia. The patient, a girl aged seventeen, had great pallor, with slight swelling of the upper part of the body and face, and considerable œdema of the legs. The hæmoglobin, estimated with Fleischl's apparatus, was only ten per cent. The œdema disappeared rapidly, and with iron the hæmoglobin rose, in two months, to normal. Surely we have here a not uncommon illustration of the œdema associated with an impoverished blood,

and of which we see marked instances in chlorosis, and in the anæmia of cancer. So striking may the dropsy be in the former disease, that we have known cases treated for months as instances of Bright's disease.

The etiology of this essential dropsy is as yet unknown, a majority of the cases occur after severe exposure and cold, and some of the cases doubtless come in the category of the *anasarque rheumatique* of the French. Many instances have followed the infectious diseases, and it is well to remember that there may be, as Quincke has shown, anasarca after scarlet fever without albuminuria. The three post-mortems in Wagner's cases gave no clew to the pathology of the disorder. A neurotic theory has usually been called in to explain the phenomenon, but we have no satisfactory evidence how œdema can be produced by disturbed vaso-motor action. On Cohnheim's view we must suppose some widespread alteration in the vessel walls, but in what way brought about, whether through nervous influence or by the direct action of such an agent as cold, it it impossible, in the present state of our knowledge, to say. The condition has not only a great theoretical interest, but also a very practical aspect as the cases would appear to be not uncommon, and must be separated carefully from those of renal, cardiac, and hæmic origin. Fortunately, as Wagner shows, the disease in adults is very rarely fatal.

CLEAN HANDS.

At the present day the medical idea of cleanness is freedom from germs. The difficulty of realizing such a state lies in the carelessness engendered by superficial observation, which leads one to look on infection by the hand as very rare, and in the too minute requirements of those who desire to achieve the impossible. The subject of bacterioscopically clean hands has been carefully considered by Kümmell, Gärtner, and Förster, but the latest and most complete, as well as the most practical contribution is by Fürbringer (*Untersuchungen und Vorschriften über Desinfection der Hände des Arztes*, etc., Wiesbaden, 1888). Those who dwell in the Happy Valleys of "Asepticism" will find in his article nothing worth reading; but others, and especially those led by the exigencies of practice, or the struggle for existence, from the autopsy to the puerperal chamber, or from the not eminently aseptic rectum, or vagina to the casual laparotomy, may find it profitable.

Fürbringer was guided in his researches by a knowledge of the fact that the "subungual space," or that included between the free end of the nail and the finger pulp, is the most difficult part of the hand to clean. Even when incapable of infecting the usual artificial culture-media, this space can harbor germs which in the warm fluids of wound surfaces, or the peritoneal cavity may, in the act of operating or touching, be washed out. He therefore endeavored to ascertain how to sterilize perfectly the subungual space. Experiments showed that the disinfectant action of carbolic acid, or sublimate solution did not depend on the strength of the liquid alone, but that the most essential thing of all was a preparation of the skin and the nail. Actual contact of the germicide with the skin does not take place when the latter is dry, and as the result of many experiments Fürbringer added alcohol to the toilet of the hands. His whole method, which is said to give almost ideal results, is as follows: 1. The nails are mechanically cleaned of all visible dirt. 2. The hands, especially the nails, are scrubbed with warm soap and water, by means of the brush. 3. The hands are immersed for one minute in alcohol (at least 80 per cent.), and while still wet, 4. Plunged into 2 per cent. bichloride, or 3 per cent. carbolic acid solution, and kept in it one minute.

The advantages of this method are: Security of disinfection, sparing of the hands, and economy with use of sublimate, which Fürbringer prefers to carbolic acid. The amount and form of the bichloride solution were matters of careful and exact experiments. We may add that this method is now used in von Bergmann's clinic, already famous for its admirable antisepsis.

CHRONIC POISONING BY COFFEE.

Many of the medical profession for years have been called upon to treat a large class of half-starved women, chiefly poor seamstresses, who are accustomed to carry on the most severe toil with scarcely any other food than crackers and tea. As a consequence of this lack of nourishment, the tea simply aids the woman in using up not only the vital force of daily life but also the reserve powers, which for the maintenance of health must always be present.

Symptoms, therefore, arise in these cases dependent upon two causes: the first of which is exhaustion, the second teaism. It would seem to be doubtful whether the tea itself is ever purely the

cause of the ailments frequently ascribed to it, since it is the very condition of exhaustion which enables the beverage to affect, to any great extent, the general system, save in those cases where enormous amounts are ingested.

We desire now to call attention to an analogous condition produced by coffee, and to which GUELLIOT, of Reims, in the *Revue générale de Clin. et de Thérapeutique* of December 15, 1887, gives the name of coffeeism. Curiously enough, coffeeism would seem to be present rather in the well-to-do and well-fed class than in the class affected by teaism, yet it is evident on comparing the symptoms noted by Guelliot, with those reported some time since by Bullard, that little difference exists between them.

Chief among the disorders produced by coffee we find anorexia, and this symptom also led the list of Bullard. Sleeplessness and nervous tremblings stand next in frequency of occurrence, while a long train of disorders arising from disturbed nutrition and assimilation follow in various forms. In the treatment of this condition, the first object of the physician is, of course, to prevent the ingestion of any more coffee if possible, or at least to limit its use. Further than this the symptoms must be treated as they arise, general hygienic measures must be insisted upon, and, as a general rule, owing to the class of persons suffering from this disorder, exercise is indicated rather than the "rest-cure," as is so frequently necessary in "teaism." Where the sufferer has used coffee with the object of aiding him to carry on some nerve or cerebral strain, this indication is, of course, reversed; but in the fat and heavy gourmand whose emunctories are clogged, whose digestion is disordered, and whose general system is reeking with the results of imperfect elimination of tissue waste, the reduction of the amount of coffee, and plain living with exercise are the chief measures by which to obtain relief.

Notwithstanding the researches of the chemist which prove that caffeine and theine are identical, it must not be forgotten that along with the caffeine in a cup of coffee one takes into the system some of the empyreumatic oil belonging to the bean, the general influence of which is at present unknown, save that it is possessed of sufficient power to influence the system very markedly.

REVIEWS.

DOCTOR AND PATIENT. By S. WEIR MITCHELL, M.D., LL.D. Harv., etc. 12mo. pp. 177. Philadelphia: J. B. Lippincott Company, 1888.

IN a half-dozen essays the author embodies the salient features in the relationship of doctor and patient, among that peculiarly challenging class of invalids, nervous women; with whom he has had so much to do.

His avowal that he was tempted to call these essays lay sermons reminds us of the remark made by a gifted and suffering woman, "The physician is the priest of the 19th century, and is far more the father confessor of women than the clergyman." Retaining the metaphor our author first lays aside the formal robes of his office, and in simple garb discusses the physicians of two centuries ago, and finds in their wisdom the same saving leaven of physiological good sense which leavens the best knowledge of to-day. He tells us not only what the good physician was, but what, in the light of modern accuracy, he should be, and urges the high ideal of the most thorough discharge of duty, the exercise of the most discriminating sympathy, and liberality of culture upon us.

Then, "from grave to gay," he recalls the pleasures of convalescence, and so brightens anew the brightest link in the bond of physician and patient. But, recollecting his office, he becomes again the priest of suffering, and turns upon the manysided problem of pain, the clear light of extensive and careful observation. He does not forget children, and would treat, not only material but mental disease in them by securing above all the moral coöperation of parents and caretakers.

Certainly none can speak more knowingly than he of nervousness and its influence on character, and *ex cathedra* the duty of self-control and patience in suffering is strongly urged. It is interesting to know the author's view, that, regarding the differences between men and women, for him, "the grave significance of sexual difference controls the whole question;" a significant commentary upon some methods of educating women in vogue at present. And last, to complete a cure, the services of that old and tried nurse of the human race, Dame Nature, are invoked, and life for women, in tents and cabins, is sketched so happily that they can hardly resist the invitation.

There is no one more commonly discussed than the doctor, and few, indeed, are they who are not at some time patients; and for the profit and pleasure of both these essays will prove most suggestive.

THE RECTUM AND ANUS. By CHARLES B. BALL, M. Ch. Univ. Dublin, F.R.C.S.I., Surgeon to Sir Patrick Dun's Hospital, etc. 16mo. pp. viii. 410. Philadelphia: Lea Brothers & Co.

A CAPITAL book in a capital series of clinical manuals. Thoroughly practical, it is both comprehensive and condensed, and the possessor of it will find but little use for any more extended work upon the subject of which it treats. Based upon a large personal experience as the book evidently is, its author has been as well a diligent student of the writings of other observers, and he presents with fairness and sufficient fulness the views of those who have the right to be regarded as authorities.

Nor is there the least sign of national prejudice or insular narrowness, but in the spirit befitting the subject of an empire encircling the globe Mr. Ball quotes freely from American, German, and French authors. The result is that the reader feels that he has in his hand a book that he can trust to contain all and the most recent information that is worth having. Indeed, upon a careful examination we find no omissions of any consequence, and are impressed by the combination of minute detail, and terse condensation which marks the book. Such a combination is attainable only by one who is thoroughly master of his subject, and it inspires the reader with full confidence in the fitness of the author to direct and guide. This confidence is not misplaced, as Mr. Ball is not only a full man, but a most sound surgeon.

Calm and judicial in the estimates he places upon differing modes of treatment, Mr. Ball gives his own views with candor and clearness, and these views will be found to commend themselves very generally to practical surgeons of experience. In fine, we have utterly failed to convey our meaning if the reader does not perceive that we hold this book in high estimation, and we would freely commend it as a very good book on a most important topic. Adding that the illustrations are good, sufficiently numerous, and really illustrate the text, we end by saying, buy it, read it, and differ from it most cautiously.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 19, 1888.

THE PRESIDENT, A. JACOBI, M.D., IN THE CHAIR.

DR. T. R. POOLEY read a paper on

THE INDUCTION OF PREMATURE LABOR IN AMAUROSIS AND AMBLYOPIA FROM ALBUMINURIA IN PREGNANCY.

He said that disorders of vision associated with pregnancy have not received the attention which, from their importance, they deserve. Such disorders are more apt to occur in the later months of utero-gestation, and the sight is sometimes permanently lost. Vision may be affected in two ways. *First*, a sudden amaurosis, and, *second*, a gradual impairment, but not complete loss of sight. Like kidney disease, these disorders of vision in pregnancy have been long known, but not until recently has it been preferred to induce premature delivery for sight alone. As to the propriety of this procedure and the indications for its adoption, these can best be settled on scientific grounds by the coöperation of both obstetricians and ophthalmologists.

The honor of first proposing the induction of premature labor in these cases belonged to Dr. Edward G. Loring, of New York, who, in 1883, published the history of a case in which labor was prematurely induced for atrophy of the optic nerve depending apparently on rapidly recurring pregnancies. The patient was thirty-five years of age at the time, and one eye was already blind. Fearing the loss of the other eye, he proposed the operation. In this case the usual symptoms of albuminuria were entirely absent; but Dr. Pooley thought it possible that the disease of the eye was really dependent on uræmia, as there was no reason why optic neuritis should not occur from obscure disease of the kidney.

Having referred to cases reported by Lee and Eastlake, of England; Holmes, of Chicago; and O. W. Moore, Arango, and Callan, of New York, and himself, he went on to say that if the patient was allowed to go to full term, permanent blindness, or serious impairment of vision might occur; while, if premature labor were induced, or took place spontaneously, improvement always followed, and in some instances the sight was entirely restored. In many cases of the neuro-retinitis of Bright's disease, it seemed as though nature attempted to relieve the patient by bringing on premature labor; but where this did not take place spontaneously, the artificial induction of labor was justifiable, and even demanded.

Having quoted Dr. Loring on the medico-legal aspects of the operation, Dr. Pooley gave his conclusions as follows:

First. In all cases of pregnancy, not only should examinations of the urine be systematically made, but the eyes should be examined with the ophthalmoscope; since, in a large proportion of cases, where eye troubles exist, the patients make no complaint of disorders of vision. Frequently such troubles can be detected with the ophthalmoscope long before any disease of the kidney is shown in the urine.

Second. In uræmic amaurosis, without changes in the eye visible to the ophthalmoscope, even should the usual accompanying symptoms, such as dizziness, nausea, and threatened convulsions, be absent, their supervention is soon to be anticipated, and the immediate induction of premature labor is indicated, without waiting until the life, as well as the sight of the patient is in danger.

Third. In neuro-retinitis the induction of premature labor is not only justifiable, but urgently demanded. In some instances it is called for even in the earlier months of pregnancy.

Fourth. It is required in cases of eye trouble recurring in successive pregnancies, like Loring's.

Fifth. A woman having once suffered in this way during pregnancy, the relationship of cause and effect should be fully explained, both to herself and her husband.

DR. EDWARD G. LORING spoke of the necessity of early ophthalmoscopic examinations in all cases of pregnancy, and said that it is a very simple thing, which every practitioner could readily become familiar with, to detect the retinitis of Bright's disease. Statistics show the very great frequency with which the retina is affected in pregnancy, and it is important that the trouble should be promptly recognized. This inflammation may begin very early in pregnancy, while disease of the nerve may not occur until many months after the labor. He then spoke of a very peculiar condition not associated with *retinitis albuminuria*, which originates not from pregnancy, but from uterine disturbances. Thus, a girl of eighteen was found to be losing the sight of one eye, and an examination revealed atrophy of the optic nerve on that side. As she was suffering from amenorrhœa, every effort was made to restore the menses, and the measures adopted proved successful. One year later the other eye became affected, and on examination now showed nearly complete atrophy of the optic nerve on one side, with retino-neuritis on the other. The menses, which had again ceased, were once more restored, and afterward

she was married, and had a child. After she had been nursing the infant for about three months, she began to have trouble again in the sound eye. She was advised to wean the child at once, and when she had done so the menses came on. She is now pregnant again.

DR. BARUCH said that he was in accord with Drs. Pooley and Loring in regard to the propriety of inducing premature labor in the class of cases referred to. Life is as much in danger as the sight, and, therefore, he thought the necessity for it is plain. The disorder of vision is a danger-signal which warns the practitioner not to neglect even small symptoms. If amaurosis or amblyopia is present, the condition depends on nephritis, and there are, therefore, many reasons why the pregnancy should be prematurely terminated.

DR. MURRAY thought that all the deductions of the paper were hardly justified by the facts of the case, so far as known, since a very small proportion even of those who suffer from eclampsia become blind. It seemed to him unnecessary to subject all pregnant women, whether they complained of any disorder of vision or not, to the inconvenience of an ophthalmoscopic examination.

DR. GEORGE T. HARRISON said that the paper seemed to show the close relations that exist between different specialties in medicine, and that he had been convinced by it that obstetricians should pay more attention to the vision in pregnant women. In practice it is important to make a distinction between *nephritis gravidarum* and *nephritis in gravitate;* the first being a form of disease in which the anatomical and functional disturbances of the kidneys are evolved by the state of pregnancy, while the latter is an interstitial or parenchymatous nephritis, which either existed prior to conception or has been produced by causes other than pregnancy during the course of the gestation, and in which abortion or premature labor is apt to occur spontaneously. It was evident from what we had heard this evening that the ophthalmologist is able to throw considerable light on this subject.

DR. POOLEY in closing the discussion said he had already written a paper on the subject of eye-disease dependent on uterine disturbances, alluded to by Dr. Loring, in which he had reported some cases observed by himself, and that he had, therefore, not referred to that subject in his present paper.

SECTION ON PEDIATRICS.

First Scientific Meeting, January 25, 1888.

J. LEWIS SMITH, M.D., CHAIRMAN.

DR. A. CAILLÉ presented a

CASE OF GENERAL MUSCULAR CONTRACTURE

in an infant six weeks old which had been seen by him for the first time that afternoon, and said that it seemed to him that the condition present was probably due to an arrest of development *in utero*. The parents were both healthy, and this was their third child; the other two children being strong and well-developed in every way. As far as could be ascertained there was no syphilitic or other taint in the infant, which was born at full term. The head was large with a decided flattening on one side of the cranium, but the rest of the body was small and shrunken in appearance. The jaw, which was turned somewhat to one side, could be opened to only a very limited extent, and there was contracture of the muscles of both the upper and the lower extremities.

DR. A. JACOBI, after an examination of the infant, which was exhibited to the Section, said that he could not see any evidence of arrest of development, and that the condition present appeared to him to be the result of a meningo-encephalitis occurring during fœtal life. The contracture of the jaw somewhat resembled that seen in incipient trismus, although the spasm was not so marked as in that condition. The appearance of the cranium was very much like that seen in cranio-tabes in children a year or more old. He thought that it was doubtful whether galvano-electric treatment would be of much service in such a case, and that an unfavorable prognosis must be pronounced, although a certain proportion of children presenting the condition noted in this infant, which was undoubtedly very rare, recovered.

THE CHAIRMAN exhibited a

CASE OF INFANTILE PARALYSIS

which he believed to be due to polio-encephalitis. The child was two years old, and had always been perfectly healthy, with the exception of an attack of diarrhœa, up to May last, when, at the age of sixteen months, while apparently perfectly well, it was seized with violent convulsions, which lasted from 6 P. M. to 9 A. M., and were accompanied with considerable febrile movement. After the stupor commonly following severe eclampsia had passed away it was found that the child had complete paralysis of the muscles on the left side, including the facial muscles on the same side. The recovery from the facial paralysis was complete and had taken place rapidly, while there had been a gradual improvement as regards the muscles of the upper and lower extremities. At the present time the child is able to walk, though partly dragging the left leg, while there is still a spastic condition of the toes of the left foot.

DR. SMITH said he was of the opinion that some of the cases resembling this, which had been reported as due to cerebral inflammation, were in reality instances of cerebro-spinal meningitis. Since 1871 epidemic cerebro-spinal meningitis had obtained a permanent foot-hold in New York and children were constantly liable, therefore, to be attacked with this disease. In the present case, however, the patient resided on Long Island, and, consequently, not being subject to influences giving rise to cerebro-spinal meningitis, he thought the latter might be excluded here. It was thus evident that the condition must have had a local cause, and, judging from the history of the case and the symptoms described, particularly the fever accompanying the sudden attack of eclampsia, he was inclined to the opinion that it was one of infantile cerebral paralysis or polio-encephalitis, as described by Strümpell. One of the characteristics of this affection pointed out by the author named was that tendon reflex not only remained, but was exaggerated, and this was found to be exaggerated in the present instance.

DR. B. SACHS said that it seemed to him that simple meningeal hemorrhage would offer a more satisfactory explanation of the phenomena noted in this case than polio-encephalitis. As a result of the latter condition there almost always followed more or less mental impairment, while after meningeal hemorrhage the condi-

tion of the mind remained unaffected, as was the case in this instance. Still, it was by no means certain what the exact diagnosis was here, and he thought that it would be impossible to arrive at any definite conclusion until a study of the electrical reactions of the case had been made.

The Chairman stated that it was the marked febrile movement described as accompanying the eclampsia, which had principally led him to decide in favor of polioencephalitis.

Dr. Francis P. Kinnicutt said that he believed that many cases like this were due to embolism. Abercrombie, in reporting a number of cases of infantile paralysis, recently, in one of the English medical journals, had expressed the opinion that a certain proportion of them depended on embolism; and Goodhart, while acknowledging other sources of origin in many instances, also ascribed some of the cases to this cause. It seemed to him, therefore, that the possibility of embolism should always be taken into consideration, and particularly when children are in an asthenic condition, as after attacks of the exanthemata.

Dr. Jacobi said that in asthenia from the eruptive fevers we should expect thrombosis rather than embolism. If there were heart disease, or even a broncho-pneumonia, we might believe then an embolus was the cause of the paralysis, but otherwise he thought this was to be excluded. Thrombosis, however, is a very common result after exhaustive diseases. As to the advantage of studying the electric reactions of the present case, he hardly thought that much light would be thrown on it by such an investigation.

Dr. Kinnicutt said that he should have explained that in embolism occurring in the asthenic conditions referred to, he should attribute the embolism to thrombosis occurring in some distant part.

The Chairman said that in this case thrombosis and embolism could be excluded on account of the previous good health of the child.

Dr. Landon Carter Gray, of Brooklyn, said that the exact diagnosis of hemiplegia in children is environed by much obscurity. Personally he was very doubtful whether the condition described by Strümpell occurred very often, and he believed that the statements which he made were founded, to a large extent, merely on speculation. The most that we could say was, that in children the site of the trouble is apt to be in the cortex of the brain, and usually in the motor region. It is generally impossible to make a differential diagnosis, and at autopsies he had more than once congratulated himself that he had not attempted to decide between encephalitis and meningitis during life. The whole matter is entirely uncertain, and in the present state of our knowledge, on account of the great liability to make mistakes, he thought it more scientific not to venture upon a precise diagnosis in such cases. From a practical point of view it makes very little difference what is the exact condition present.

Dr. A. Seibert then read a paper entitled

A CONTRIBUTION TO THE STUDY OF CEREBRAL PARALYSIS IN INFANCY.

After a brief introduction, he said that in 1885 he was called upon to examine an infant two and a half months old. It was the seventh child of its mother, all the others having been healthy children, and there was no evidence of syphilitic or tubercular trouble. The mother stated that during her pregnancy, when she was carrying this child, she scarcely ever felt life, and that when the infant was born it was asphyxiated, and had the cord tightly wrapped twice around its neck. It was very different from her other children at the time of birth, being small and flabby, and for two months it never stirred or cried. When two and a half months old it had an attack of capillary bronchitis, and it was at this time that it first came under Dr. Seibert's notice.

At the age of ten months it was still in practically the same feeble condition. It lay quietly on its back, the skin was wrinkled, and the respiration was noted to be for the most part diaphragmatic. There was no evidence of cranio-tabes. The pupils were narrow and equally dilated, and the constant expression on the child's face was that of a dreamy, vacant stare. When the body was raised to an upright position the head would fall to that side on which there was the greatest incline. The intercostal spaces were very narrow, the intercostal muscles took but little part in the act of breathing, and there was a deep furrow in the region of the diaphragm. The muscles of the neck were but mere strings, and there was in general an almost complete absence of muscular power. The infant never had any convulsions.

From the phenomena thus presented it was evident that there was an atrophied condition of the brain, and Dr. Seibert endeavored to find out the cause of this. Meningitis was at once dismissed, as this condition had existed from birth; for if it had been due to meningitis this must have occurred during fœtal life, and, so far as he was aware, this was something which had never been noted. Neither did he think that the trouble was due to hemorrhage. The child was small, flabby, and atrophic when born. All the symptoms denoted an atrophic condition of the whole body, including the brain, at the time of birth and after birth. The muscles of the neck were more completely atrophied than any others, and in this connection it was significant that the infant had been born with the cord wound twice around the neck.

In this constriction of the neck by the cord, it seemed to him, was to be found the solution of the case. By means of this the blood supply of the head and brain had been to a great extent cut off, and this would abundantly account for the cerebral atrophy and the general lack of nutrition in the child's body. At the time of birth the bloodvessels of the head, which had long been comparatively empty from the pressure of the cord around the neck, suddenly became filled when this was removed, and hence the aphyxia noted.

At fourteen months of age the child died from another attack of capillary bronchitis, and when the brain was examined after death it was found that the layer of white matter was very thin, and the diagnosis of cerebral atrophy was fully confirmed. In the course of his experience he had met with four cases altogether in which there was a congenital atrophic condition of the brain, but only in this instance had he been able to secure a full clinical history and verify the diagnosis by autopsy.

The second form, he said, is more common than the first, and of this he gave a detailed description of two cases. In one of these a post-mortem examination was made, but not in the other. In this second class of cases the symptoms are similar in character to those met

with in the first; but here they are brought about by pathological changes; viz., meningitis with exudation, arachnoid thickening, and sometimes moderate hydrocephalus. The results of the meningitis cause atrophy of the brain. The symptoms of defective innervation always remains the same whether the cerebral atrophy is congenital or is the result of subsequent meningitis.

The third class of cases mentioned is characterized by incessant crying and moaning, with muscular contractures and sometimes permanent opisthotonos, though there are no general convulsions. The condition is due to chronic meningitis, steadily increasing, and causing abundant exudation over the cortex, but running its course without febrile movement. He related two cases of this kind, occurring in a brother and sister, and in one of them the diagnosis was confirmed by autopsy. After lasting for several months the affection terminated in heart failure, the temperature in one case falling at the time of death to 96° F., and in the other to 94°. In the case in which the post-mortem was held there were no tubercles or tubercle bacilli present.

In conclusion, Dr. Seibert said that in these three classes of cerebral paralysis of infancy the clinical manifestations were all due to atrophy of the brain, although in the first the original cause of trouble was insufficient blood supply, in the second, acute meningitis, and in the third, chronic meningitis.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, January 11, 1888.

The President, J. Solis-Cohen, M.D., in the Chair.

Dr. Charles K. Mills read a paper on

THE TREATMENT OF NERVOUS AND MENTAL DISEASE BY SYSTEMATIZED ACTIVE EXERCISES.

Exercises or movements for medical purposes—medical gymnastics, in other words—have been divided and subdivided to an absurd degree by Ling and his followers. Schreiber gives an example of a German term for what is called the quarternary combination of the standing position, which term contains forty-five letters and nine different words, although it is written in German as a single word. The division, however, into such movements or exercises as passive, duplicated active, and active, is rational and useful.

It was of systematized active exercises, that Dr. Mills more particularly wished to speak. The expression single active movement indicates that the movement is performed by a single individual without direct assistance, although it may be done under the orders of a physician or master. Exercise of this kind may be performed either with or without apparatus, and even when the latter is used it need not necessarily be expensive.

Dr. Mills next briefly reviewed the literature of medical gymnastics, and described various forms of pulley-weights and other apparatus. He made use largely of the forms of respiratory exercises described by Blaikie on *Sound Bodies for Our Boys and Girls*, sometimes without and sometimes with apparatus.

The treatment should begin with the simplest forms of exercise, and these should be constantly increased and elaborated, as the patients gain in skill and strength. It is wonderful how little some patients can do in this direction. A grasshopper in gymnastics is a burden to them. Five minutes or even less, is sometimes all the time that can be safely taken at first, and five minutes of actual exercise must sometimes be distributed over half an hour. In most cases the time should never be allowed to exceed twenty to thirty minutes. Often it is important to give resting spells during the process of treatment. Some patients, ambitious to excel or fearing to appear weak, will certainly overdo. Individual peculiarities should be carefully studied. In the majority of cases of nervous and mental diseases in which systematized active exercises are indicated, the danger will be greater of overdoing than of doing too little.

The paper was not founded simply upon theoretical considerations and a study of literature. For several years Dr. Mills had, to some extent, used systematized active exercises, either with or without apparatus, and during a year past he had had a considerable number of patients on this treatment. His objects, in addition to recording experience, were to call general attention to a too much neglected method of treatment, and to make certain practical suggestions which naturally grew out of a study of the subject. When preparing this paper he was able to put his hands on forty-four such cases, not including those under treatment at the Philadelphia Hospital. Of these cases, twenty-five were treated by the general active exercises, some with and some without pulley-weight apparatus; the other nineteen by some local method for a special purpose. The patients treated by the general exercises included cases of idiocy, insanity, asthma, minor chorea, habit chorea, hysteria, general nervousness, neurasthenia, nervous palpitations, lithæmia, cerebral syphilis, diabetes, curvatures, ataxias, and paralyses; those treated by special more or less local methods included cases of hemiplegia or monoplegia, infantile paralysis, lead paralysis, rheumatic neuritis, muscular atrophy, aphonia, and writer's or telegrapher's disease.

Much could be said, did time permit, about the beneficial effects of regulated physical culture in idiocy. For the improvement of the general nutrition of a class of unfortunates, usually deficient in this respect, as well as for their training and development, both mental and physical systematic exercises are of the utmost value. In some grades of idiocy attention should be paid to individualizing the treatment by exercise. To a certain extent gymnastics can be used for diagnostic and prognostic purposes in idiocy, observation of those attempting systematized exercises determining the possibilities as to general improvement.

A few weeks since, in the Insane Department of the Philadelphia Hospital, Dr. Mills had started a class in systematized active exercises, selecting eight women suffering from melancholia, and putting in with them to give zest to the treatment two other cases not mentally depressed. Sufficient time had not yet elapsed to determine how much in a curative way could be accomplished by such treatment, but already the experiment had proved an instructive one. He found that even these patients, plunged into the profoundest depression, could, by sufficient persistence, be aroused to the performance of some movements; others did moderately well; some very well. The difficulty of fixing the attention of these patients, and yet the possibility of doing it by sufficient effort, had been clearly shown. The class had made much im-

provement in facility and rapidity. Small classes should be formed in large insane asylums, and the treatment given a thorough trial.

Systematized active exercises serve a good purpose in some of the various disorders designated as asthma. One case of this kind, a young lady, despondent, weak, dyspeptic, hysterical, with feeble heart, and subject to attacks of asthmatic breathing, improved with great strides in a few weeks under general active exercises. She began treatment with half-pound dumb-bells, and at first could only stand five minutes' work. The exercises were increased, until half an hour was reached, and dumb-bells weighing four pounds were used.

In the treatment of chorea, or rather choreas, systematized active exercises are valuable. Special forms of gymnastics have been employed for this affection particularly in France and Germany, to a large extent, by Napoleon Laisné, a French professor of gymnastics, and evidently an earnest and enthusiastic worker in his chosen field.

Two cases of minor chorea improved under medicinal treatment up to a certain point, and then would advance no further. General exercises with light dumb-bells were ordered, and in both cases the progress to complete recovery was rapid. In the treatment of habit chorea, he found the exercises have a peculiar value.

The advantage of any treatment which involves specific direction and the adroit calling out of the volition of a patient must be evident to everyone who has had experience with hysteria in its manifold forms. In hysterical paralysis much can be done by laying out a careful plan of treatment by exercises, and gradually leading up to their full performance. For the improvement of nutrition, and of what may be termed the general nervous and mental tone of hysterical patients, systematized active exercises fill an important place. Properly used and controlled, they may also prove most beneficial for cases of general nervousness, and also for neurasthenia. Whatever view may be taken of the much mooted question of neurasthenia, without doubt both respiratory and muscular power, either primary or secondary, is often deficient, and the nerve centres themselves can be strengthened and improved by exercising these two powers. Care should be taken not to force individuals suffering in this way to excessive effort at first.

For the group of diseases which fall to the lot of both the neurologist and orthopædist—cases of curvature, deformity, atrophy, etc.—systematized active exercises have long been used by the best authorities. The more particular object was to call attention to the value of systematized respiratory exercises in setting up or straightening the feeble and stooped, who also frequently are sufferers, in some degree from nervous or mental weakness. If, at the same time, appropriate general hygiene is used, the improvement in such cases is sometimes simply wonderful.

For gout and lithæmia, to promote excretion and nutrition; for anæmia and spanæmia, to assist assimilation and further oxidation; for headache, sleeplessness, and nervous irritability, to soothe and calm the nervous system; to aid elimination in cases of lead, arsenic, mercurial, and other metallic or toxic diseases; for diabetes, to favor the skin and increase combustion, systematized active exercises have a value which cannot be too highly extolled, and one which Dr. Mills had had an opportunity to demonstrate in his own practice.

In curable ataxias, as in those which follow diphtheritic or exanthematous diseases, and in the hysterical varieties, systematized active movements, the patient at first lying down or sitting, and subsequently standing, had proved of great service.

In patients suffering from multiple neuritis, or some curable forms of myelitis, advantage should be taken of the first signs of motor improvement to begin with active exercises, while the use of electricity and massage is continued. The particular point upon which it was desired to insist, was that the attempt to join the will of the patient to the long unused muscles, should not be deferred a moment longer than was necessary. Simple attention to this truth, which ought to be self-evident, would in many cases have saved patients from weeks or months of uselessness.

In the treatment of various forms of paralysis, that systematized active movements may be employed with advantage has long been known. Even in paralysis from organic brain disease, a clear method of using gymnastic treatment will be found to serve an excellent purpose.

For some of the arthritic neuroses, and for rheumatic neuritis, or muscular rheumatism, these exercises are of undoubted value. Dr. Mills saw three cases of a form of rheumatic neuritis affecting the deltoid and adjoining muscles, in which the progress to complete recovery was much assisted by an early resort to dumb-bell exercises and pulley-weights.

Hysterical aphonia or apsythria (loss of the power of whispering) can sometimes be treated successfully by a species of respiratory gymnastics, or a combination of respiratory with vocal and muscular gymnastics.

In certain cases the treatment by rest, seclusion, etc., could be successfully combined with that by systematized exercises. After the nervous or broken-down patients suitable for the treatment have progressed to a certain point; after their nutrition has been placed upon a firm basis, respiratory exercises without apparatus, or with very light dumb-bells, could be carefully begun. Five minutes, or perhaps only three minutes, should be taken at first, and the time should be increased with the utmost caution. In a recent neurasthenic case with hystero-epileptic seizures, after the patient had improved under the rest treatment, systematized active exercises were resorted to with the greatest benefit. In those cases of hystero-epilepsy in which the seizures are partially voluntary, or of the induced voluntary kind, the use of such exercises assists the patient in obtaining that control of herself and her movements which enables her to resist the beginning of the attacks.

CORRESPONDENCE.

INTRACAPSULAR REMOVAL OF THE SPLEEN.

To the Editor of The Medical News,

Sir: In The Medical News of January 21, 1888, in an editorial entitled "Inaccuracies in the History of Splenectomy," attention is called among other things to an operation in 1711 by Ferreri which consisted in opening an abscess of the spleen. The paragraph ends with the statement that a similar case occurred quite recently in this country. A case occurring recently in this city, in which I was the operator, is probably the one referred

to. I shall report this case in full at a later date under the title of "Intracapsular Removal of the Spleen." Briefly the points in the case are as follows: The patient was a married woman, aged twenty-nine years, presenting a large spleen extending to within an inch of the crest of the ilium and beyond the median line. The cause was an hydatid cyst. For two weeks prior to operative interference she had a temperature of 105°. On October 4th, 6th, and 9th I aspirated the cyst. I then determined to open the spleen, and on October 14th performed splenotomy through an inch and a half abdominal incision. October 28th I made a counter-opening at the free end of the lower rib.

At various intervals I removed with finger and dressing forceps accessible portions of spleen; at one time removing in bulk as much as a normal spleen. December 2d, a week after I had ceased to be able to remove any more by the finger or forceps, a characteristic sloughing process began which ultimately removed the last of the spleen—a small portion which I had located in the most posterior part of the cavity close to the diaphragm.

Very severe hemorrhage, most profound anæmia, and an almost fatal attack of pneumonia complicated the case. January 12, 1888, the primary wound was allowed to close, the counter-opening will be closed in a few days. The patient is sitting up, eating better than for five years, and sleeping better than for two years.

I take this means of calling attention to the case to correct an impression caused by an inaccurate newspaper report. I did not open an abscess of the spleen, nor did I perform a technical splenectomy. The operation was done to let out the contents of an hydatid cyst, the sac of which was highly inflamed. On opening the spleen it was found that the sac had ruptured, and the contents had rendered the spleen so septic as to indicate its early removal. While awaiting consent to a technical splenectomy I determined to remove portions of the organ gradually until urgent symptoms might compel me to desist. One danger always beset me, that from hemorrhage, but I always succeeded in checking it before it became dangerous. The condition of the capsule, thickened from capsulitis, was an element of safety in the case; although for the same reason retraction of the capsule and consequent contraction of the cavity was delayed. The subsequent history of the capsule I will refer to at a future time. I have, in the pathological laboratory of the Jefferson Medical College, some considerable sized pieces of the spleen with the remains of the cyst wall to show when occasion requires.

In concluding this letter I would ask if this is not the first case on record in which a spleen has been gradually but deliberately removed from within its capsule.

Respectfully yours,

ANDREW J. DOWNES, M.D.

PHILADELPHIA, January 24, 1888.

THE DIURETIC INFLUENCE OF STROPHANTHUS.

To the Editor of THE MEDICAL NEWS,

SIR: Your editorial note under the above heading in a late issue of THE MEDICAL NEWS is rather misleading, because it overlooks the work of Prof. Fraser, the real discoverer, as well as the clinical observations of others who have given the matter very careful attention; and with your permission, I should like to correct the erroneous impression which obtains regarding a most important remedy.

You say, "So much has appeared in the journals during the last few months concerning strophanthus and its effects on the heart, that its action on the rest of the system has been overlooked." In reply to this let me refer you to the paper of Prof. Fraser, published in the *British Medical Journal* of November 14, 1885, where he reports five cases treated by strophanthus, in two of which the diuretic action of the remedy is noted as follows: (1) The amount of urine was found to be 13 ounces and 27 ounces respectively, on the two days preceding the administration of strophanthus. The remedy was begun on January 24, and on that day the amount of urine voided was 22 ounces; on the 25th it had increased to 42 ounces, on the 26th, to 96, on the 27th, to 152, and for the succeeding twelve days it ranged in amount from 63 to 109 ounces daily. (2) In the next case the average quantity of urine voided in the two days preceding the use of strophanthus was 27 ounces, but on the day following it was increased to 55 ounces, on the second day to 58, on the third day to 70, on the fourth day to 74, and on the fifth day to 82.

In a communication to this journal, published November 5, 1887, page 553, I have referred to strophanthus as a remedy "which would act principally upon the heart, and lightly upon the bloodvessels, which, like digitalis, would produce diuresis and reduce temperature. . . . As compared with digitalis, its action upon the heart is more than twenty-five hundred times greater; while on the bloodvessels its action is less than one-tenth that of digitalis." In the report of a series of cases treated by strophanthus (*Med. and Surg. Rep.*, September 10, 1887), I have spoken of the diuretic action of strophanthus, putting forward a theory to account for this specific effect on the renal function.

You say also that it has been found that strophanthus "increases the urinary flow, both by mechanical pressure, due to greater arterial tension, and also by a direct stimulation of the secreting structure of the kidney." The first part of this proposition is scarcely warranted by the facts, as I shall presently show; the second portion is granted, and judging by the work done by Heidenhain and his pupils in the way of physiological investigations respecting the renal function, I have named this "direct stimulation" *cellular activity*. My objections to the theory of "mechanical pressure," and "arterial tension," are based on clinical observation and confirmed by the experiments of Dr. Phillips with Roy's onkometer, an account of which is given in his paper read before the Ninth International Medical Congress. He says, "When the action of strophanthin on the kidney is investigated, it is found that the drug only causes a slight and temporary contraction of the organ, which soon returns to nearly, though not quite its previous volume. Thus, whereas digitalin will produce a contraction of the kidney lasting half an hour, strophanthin, on the other hand, produces a much slighter contraction, lasting only twenty or thirty seconds. Further, it does not produce any marked increase in the rate of the urinary flow, although, *à priori*, it might have been expected to do so." Dr. Phillips's experiments, although made under favorable conditions, were made upon healthy kidneys, and cannot be accepted as trustworthy guides when we have to deal with diseased conditions, an important factor

which is often overlooked. By reason of our inability to subject our patient's kidneys to the test of Roy's onkometer, we are compelled to conduct our treatment in accordance with the clinical indications, and these indications clearly point to strophanthus as a valuable and safe diuretic in properly selected cases, experimental physiology to the contrary notwithstanding.

You intimate that "cumulative effects may be found to follow its administration, when the remedy shall have come into more general use, and it is suggested that "So little is known as to the renal effects of the drug, that it is possible that it may be too irritating to use constantly in cases of kidney lesions," all of which seems to me an attempt to discourage its use, and an indirect bid for the continuance of the deadly digitalis, which has already slain its thousands and tens of thousands. When given in proper doses the effect of strophanthus is readily appreciated in the cardiac action and in the radial pulse, and within a few hours there follows a notable increase in the activity of the kidneys, conditions which point to its rapid elimination from the system. Why, then, are we required to administer strophanthus as we have been taught in regard to digitalis, with fear and trembling?

While it may be true that little is known amongst the majority of the profession as to the renal effects of this drug, this charge of ignorance on the part of those who have observed it clinically will not hold; and I venture the prediction, that its value as a therapeutic agent will be greatly extended, when it becomes more generally known. Allow me, in concluding this rather lengthy communication, to quote from a letter lately received from a well known and highly respected physician of more than forty years' standing. He says: "The peculiar properties of strophanthus are very interesting to me. . . . I have long believed, and have long taught, that the reckless use of digitalis, in all cases of heart weakness, was doing much mischief. I am glad that scientific investigators are coming to the same conclusion. My conclusions were those of an active practitioner, not an experimental physiologist."

JOHN AULDE, M.D.

4719 FRANKFORD AVE., PHILADELPHIA.
January 18, 1888.

[In reply to the above, we have only to say that we were well aware of the results of Dr. Fraser, and did not quote them because the editorial referred to was intended to call attention to the more recent studies on the drug. Dr. Fraser's experiments on man concerning the renal action of strophanthus are very limited as compared with those of Drasche and Mairet and Combemale. The results of Drasche are so closely in accord with the results of Phillips as to the influence of the drug on the normal kidney, as to be of great interest.

Moreover, the results of Phillips do not clash with the belief expressed as to the effect of increased blood pressure, for Phillips found that those drugs which increased secretion by renal stimulation produced first a momentary contraction with decreased renal flow, followed by expansion with increased flow. The very fact that the kidney contracts proves the mechanical pressure theory rather than the contrary, for every one knows that when actively at work all glands become swollen and comparatively turgid.

If Dr. Aulde has read the editorial with no more care than he has exercised in quoting us, we cannot wonder at his note. We did not state that "cumulative effects may be found to follow its administration," but that the statement of Mairet and Combemale, in denying such a possibility, could not be considered proven, "until the drug has been more widely used." Considering that strophanthus has been used and is used at present as a most lethal arrow poison, it is rather stretching a point to compare it favorably with the "deadly digitalis," of which the dose is generally three or four times the dose of strophanthus, even if the supposed attempt had been made to give the older drug any assistance.

No charge of ignorance was made, but if the writer can find the records of even one thousand of the "slain," toxicologists will certainly be indebted to him.

We note that while Dr. Aulde believes in the results reached by the experimental physiologists in the first part of his note, he rather curiously tries to decry them in the latter part.—ED.]

NEWS ITEMS.

Dr. Henry C. Coe has been appointed an obstetric surgeon to the New York Maternity Hospital, succeeding Dr. E. L. Partridge, resigned.

The Tariff on Surgical Instruments.—The Georgia Medical Society has started a "movement to remove the import duties from all medical and surgical instruments and appliances, including those used in the diagnosis as well as treatment of disease, so that they may be furnished to those needing them at the lowest possible prices," and they present the following facts to show the extent of the grievance and the justice of their plea:

1st. Physicians are at the mercy of instrument makers in regard to price, make, and quality of finish, because of the lack of sufficient competition.

2d. The price of instruments made in this country is out of proportion to that paid for similar instruments on the Continent of Europe.

3d. Surgical instruments and appliances are so costly that few entering the profession can provide themselves with an outfit adequate to carry on a general practice. At present prices it is impossible for a country physician's income to sustain his investing in costly instruments, and as a result many simple cases, such as retention of urine, foreign bodies in nose or throat, deep-seated abscesses, etc., all of which could be relieved at once with the proper instruments, must either die from the immediate cause or from the effects of time lost in seeking skilful manipulation, or else they are frequently crippled and disfigured, because the most intelligent help though patiently given is itself crippled for want of proper instruments.

4th. The cheaper grades of instruments are either antiquated or so poorly made that they may prove a cause of failure in operation, sapping, as it were, the natural inclinations to surgery in its inception.

5th. European instruments are from twenty-five to seventy-five per cent. cheaper than ours, and their introduction into the market will enable the mass of doctors to buy those of prime necessity, will bring down the price of home-made appliances, and oblige the makers to use good material, and put a better finish to their work.

6th. The removal of import duties on surgical and other instruments used by the profession, and on medi-

cines in general, will produce the same results as we all know it did on quinine.

Philadelphia Hospital.—Dr. James Hendrie Lloyd has been elected Neurologist to the Philadelphia Hospital in place of Dr. Roberts Bartholow resigned.

Death of Dr. George A. Crosby.—Dr. George A. Crosby, one of the most prominent physicians in New Hampshire, died at Manchester, on January 30th, of congestion of the brain, after a two weeks' illness. Dr. Crosby was born in Lowell, Mass., in 1831, and came from a race of distinguished physicians. He was graduated at Dartmouth in 1852. In 1857 he sailed for Peru, but stopped on the Isthmus of Panama and cared for the railroad employés, who were being swept away by cholera. From there he went to Mexico, and treated Mexicans afflicted with yellow fever. On the breaking out of the Civil War, when he returned to the United States, he volunteered and rendered surgical and medical service in camp and on the field throughout the struggle. Dr. Crosby had been President of the New Hampshire Medical Society, and was a member of the Manchester Board of Health at the time of his death.

A Prize for Pasteur.—The Turin Academy of Sciences has awarded the Pressa prize of 12,000 francs to M. Pasteur.

The Neurological Society of London has been recently organized. Samuel Wilks, M.D., F.R.S., is its president, and Sir James Crichton-Browne and Jonathan Hutchinson, vice-presidents. Its list of membership includes the best English neurologists.

The Martyrology of Psychiatry.—Under this striking heading *The American Journal of Insanity* quotes the researches of a French physician who has collected twenty-four instances of murderous assault on asylum physicians by insane patients. The list includes four Americans.

Professor Koch has been made *General-Arzt* in the Suite of the Prussian Sanitary Corps.

An Institute of Christian Science.—Professors of Christian Science, as taught in the college for this theory at Boston, have applied for a charter in Philadelphia. On challenging their right to license under the term practitioners the assertion was made that a failure to administer drugs exempted them from this classification. Further legal trial of the terms employed in licensing medical persons will undoubtedly result.

The Rewards of Medicine.—Sir Andrew Clark, of London, is reported to have said that "I worked twelve years for bread, twelve for butter, and twelve more for the luxuries of life."

Dangerous Tea.—An English wedding party was recently poisoned by partaking of tea brewed in an old copper urn. All the guests were made seriously ill, and required prompt medical care.

Professor Gosselin.—A bronze medal is about to be struck in honor of this distinguished French surgeon.

A Floating Hospital for Fishermen at Sea.—A project has been recently set on foot in England to provide a hospital ship for the fishermen in the North Sea. It is estimated that about twelve thousand English-speaking men are afloat upon this body of water, and in situations which render it difficult to obtain medical care.

Cheap Quinine.—The *American Analyst* reports that the price of quinine has been reduced from $5 an ounce to less than $1, and a dealer says it will remain cheap hereafter. The reason is that the chinchona are not destroyed in taking off the bark. Formerly the bark was stripped clean and the trees were left naked to bleed to death. Now, when the bark is removed, the trees are swathed with moss, new bark forms on them, and instead of living to bear one crop of bark they yield their bark yearly.

A Burial Reform Association.—From the *Boston Medical and Surgical Journal* of January 5, 1888, we learn that a Burial Reform Association has recently been organized under the auspices of the Protestant Episcopal Church, although it is intended that it shall be undenominational in character. Among the reformatory measures which it seeks to carry out are the following:

The exercise of economy and simplicity in everything pertaining to funerals.

The early interment of the body in soil suitable for its prompt resolution into its ultimate elements.

The use of such materials for the coffin as will rapidly decay after burial.

The substitution of burial plots for family vaults. The encouragement, on sanitary grounds, of the removal, in crowded districts, of the body to a mortuary, instead of retaining it in rooms occupied by the living.

The Adulteration of Wines.—The *American Analyst* of January 1, 1888, describes the following methods of adulteration of wines, most commonly practised by unscrupulous dealers:

The simplest one is mixing. The native wines of Ohio, New York, Missouri, and especially California, differ from those of Europe chiefly in being richer in body, flavoring, and alcohol—so rich, as to be at times coarse or harsh. A mixture of one-third light-bodied Rhine or Bordeaux wine, one-half of the corresponding California stuff, and one-sixth water will produce a liquid that is hardly distinguishable from a first-class imported vintage.

The proportions given simply apply to one case, and must be varied to suit the palate of the mixer as well as the chemical composition of the ingredients employed. Thus, one-half Santa Rosa, one-third water, and one-sixth imported Binger are used by a Fulton Street merchant to produce a fac-simile of the last-named wine. The skill and delicacy attained by these mixers is phenomenal. One, a German-American dealer, can taste any ordinary wine once and in fifteen minutes make a composition that can scarcely be distinguished from the original in color, flavor, bouquet, sweetness, and body.

A lower class of imitators dispense with the natural grape altogether. One concern on Front Street, unearthed by the New York Board of Health, in May last, was found to have its vineyard in the cellar and top loft of a vast warehouse. Here, from damaged raisins, currants, elderberries, and other cheap dried fruits it made a wine of the cheapest and vilest kind. It was so vile and

poorly made that the "viniculturist" was compelled to fortify it with spirits, and preserve it with salicylic acid to prevent its putrefaction in either glass or wood. The officials learned that he sold the execrable stuff to groggeries, cheap restaurants, and to wholesale dealers for mixing purposes, A "vineyard" of similar character in Hudson Street supplies the basing for "Beef, Iron, and Wine," "Wine of Cocoa," "Wine, Iron, and Strychnine," and other well-known medical preparations. Nor is this miserable work confined to New York City. In the *Courrier des États Unis*, this current month, are two book advertisements, one which teaches how to make a superior wine out of raisins, and the other how to make the same thing out of raisins, currants, and other materials. The books are written and published in Paris, and must have a large sale and use, both at home and abroad, when their editor finds it profitable to advertise them on this side of the Atlantic.

The Hour of Delivery.—The *British Medical Journal* writes that an industrious statistician has recently contributed to a medical journal at Lille, the results of an analysis of one thousand labors, with the precise hour at which delivery took place. He reports that 45 per cent. of the labors terminated between 8 A.M. and 8 P.M., and 56 per cent. between 8 P.M. and 8 A.M. Pushing the inquiry a step further, he found that 23 per cent. terminated between 6 A.M. and midday; 22 per cent. between midday and 6 P.M.; 27 per cent. between 6 P.M. and midnight, and 54.1 per cent. during the night—that is to say, between midnight and 6 A.M. These figures only apply to normal labors, in which nothing interfered with the physiological course, so that they go far to confirm the popular notion which admits the greatest frequency of delivery at night, "conception generally taking place at about that time."

Air Filters in Limiting the Contagion of Scarlatina.—Dr. Eccles, of Brooklyn, describes in *Science*, of January 6, 1888, the following device which he has found useful in limiting the contagion of scarlatina:

The evidence we have, indicates that the germs or spores float as impalpable dust in the air. It is found by experiment that wet gauze, by evaporation, is colder than surrounding air. Dust is attracted from warm air to a cold body. If that body is wet, it adheres. By canopies of mosquito-netting over the sick bed, kept wet with bichoride of mercury solution containing glycerine, no dust can pass through the meshes in either direction. The cooled threads attract across the narrow space of the mesh all dust that reaches there. The glycerine and water fix it, and the corrosive sublimate sterilizes it. To keep up the application, two layers of netting are required—one fixed, the other removable. The outer removable one can at stated times be wrung out of a fresh solution, and put back again. Overlapping folds can allow the passage of food, medicine, etc., to the patient. This provides perfect isolation even in a room occupied by others.

To Render Tincture of Iron Tasteless.—The *American Druggist* for January, 1888, gives two methods which are very effective in accomplishing the result desired.

1. Pour the measured quantity of tincture of iron, immediately before administering or taking it, into a sufficient quantity of *milk*, about a wineglassful for every 10 drops of tincture. This method was first recommended by Hager. The iron probably changes to phosphate in this case.

2. Pour the tincture into a sufficient quantity of *Vichy water*—about 1 fluidounce for every 10 minims of tincture. This method is often practised in the public hospitals of New York. Our attention was first drawn to it by Dr. A. B. Pope. In this case, of course, the iron changes to carbonate, the carbonic acid being speedily disengaged, and ferrous hydrate being deposited on standing. In this form it has been found to be quite easily taken, and, so far as known, with best results.

A Healthful Sleeping-Room.—Dr. Crowell, in the *Popular Science News* for January, 1888, describes a healthful sleeping room as follows:

Modern luxury has made sleeping-rooms receptacles for elegant appointments; and we find them filled with numberless articles of fanciful design—knicknacks, draperies, rugs, carpets, and every conceivable thing that æsthetic taste can invent. Hence there can be no pure air in such rooms, and the accumulation of *filth* and dust is something wonderful. While we would not strip these rooms of all artistic adornment, we insist upon simplicity; and first of all, we would discard heavy woollen carpets. They are filthy; and if the good housewife does not believe it, let her look across the room when the sun is shining through it, and see the line of dust constantly rising. Of course, this process goes on night and day, and it is unavoidable when the floor is encumbered with the woollen covering. Let the floor be laid in solid wood—birch thoroughly kiln-dried is perhaps the best—and let there be no cracks or seams for dust and vermin. A few closely woven rugs can be disposed in front of bed and toilet table, and these can be removed and shaken every day, while the floor is wiped with a damp cloth. The moral influence of such cleanliness is certainly conducive to sleep, to say nothing of the direct sanitary effects. Bare walls are better than paper hangings, even when the paper is free from arsenic; and with the soft, warm tints at the disposal of the painter, the walls can be made to glow with cheerful light.

Sinks with hot and cold water, connected with the sewerage system, should be discarded for obvious reasons; and in all houses where the fixtures pollute the sleeping-room, there should be a complete revolution in their removal. Not one in twenty of these filthy receptacles is securely trapped; and with the old devices of chain, plungers, overflow pipes, and leaky crevices, we are at variance with all sanitary rules and conditions. Let all such "conveniences" be relegated to the bath-room with open plumbing.

It is better to go back to the old washstand than to endanger the health with any such superfluous trappings. An open fireplace is not only a luxury, but a necessity as a mode of ventilation; and then, with iron or brass bedstead, with woven wire bottom and hair mattress, and with simple window-shades or shutters, we shall have a sleeping-room combining the requisite conditions for cleanliness and health.

Glucose by Synthesis.—Another important acquisition, says *Nature*, to our store of knowledge has recently been made. Glucose, commonly called grape sugar, has been

artificially prepared by Drs. Emil Fisher and Julius Tafel in the chemical laboratory of the University of Wurzburg. This happy achievement, which is announced in the number of the *Berichte* just received, is one which has long been looked forward to, and which cannot fail to give deep satisfaction in chemical circles all over the world. As is generally the case in syntheses of this description, not only has the sugar itself been actually prepared, but, what is at least quite as important, considerable light has been thrown upon that much-discussed question, the constitution of sugars. A most remarkable, and yet only to be expected, attribute of this artificial sugar is that it is found to be entirely incapable of rotating a beam of polarized light. As is well known, there are several naturally occurring varieties of glucose, all of which may be expressed by the same empirical constitution, and all possessing the power of rotating the plane of polarization; dextrose, or grape sugar, the best known of these varieties, as its name implies, deviates the plane of polarization to the right, as do several other less important varieties; while lævulose, or fruit sugar, rotates the plane to the left. But in artificially preparing a glucose there is just as much tendency for one kind to be formed as another, and the probability is that both dextro and lævo are simultaneously formed, and thus neutralize each other, producing a totally inactive mixture. It may be that, as in case of racemic acid, the two kinds are formed side by side, and neutralize each other in the solution; or it may even be, that, as is the case with truly inactive tartaric acid, there is a true neutralization within the molecule itself. Which of these hypotheses is correct is a question for further work to decide.

A Poisonous Prescription.—An Australian pharmacist recently dispensed the following prescription:

R.—Potassii chloratis . . .	gr. 40.
Syr. ferri iodidi	fl. ℥ 4.
Syrupi	fl. ℥ 4.
Spir. chloroformi . . .	♏ 20.
Aquæ . . .	q. s. ad fl. ℥ 2.

"As reported there, 'the mixture, when dispensed, was of a light-brown color, which gradually darkened, and in a few hours iodine was deposited in abundance. In this condition, the mixture was administered to a child, eventually causing death.'"

Now it is well known that, under the influence of light and air, and in the presence of water, ferric iodide constantly eliminates traces of hydriodic acid, which will, under certain conditions, decompose so that the iodine is set free, giving the solution a dark color. In the presence of sugar or certain other substances (such as hypophosphorous acid), however, the free iodine is again taken up and reconverted into hydriodic acid. As the process of eliminating hydriodic acid seems to go on continually, it appears to us that this body exerts its decomposing action on the chlorate while in *a nascent state*. But the eliminated chlorine immediately again decomposes the trace of iodide formed. We can account for the reaction in no other way, but would suggest that this subject be taken up by some one who has the necessary time to devote to its study. Incidentally we would remark that the presence of peroxide of hydrogen in the atmosphere, or the addition of peroxide of hydrogen to hydriodic acid or to the iodides causes an abundant liberation of iodine. It is not impossible that the presence of this body may have something to do with the reaction.—*American Druggist*, January, 1888.

To Clarify Muddy Water.—The *Pharmaceutical Era* for January, 1888, gives the following directions:

Charge slips of filter paper respectively with ferric chloride and with sodium carbonate, dry and preserve for use. Place one of the ferric chloride slips in the water to be clarified, and in a few moments one of the soda slips. The flocculent precipitate of ferric hydrate produced clarifies the water, which may then be filtered through a funnel whose neck is filled with a piece of sponge.

Alum may be substituted for the ferric chloride, and will give nearly as good results, but will leave a little more saline matter in solution.

Hindoo Philanthropy.—The *British Medical Journal* writes that the Maharajah of Darbhanga, in Bengal, has established a hospital and dispensary for female patients near his ancestral seat in the district of Darbhanga, Behar, and is erecting new quarters for its accommodation at a cost of 55,000 rupees, in connection with Lady Dufferin's Medical Aid for Women Fund. This is one of the least considerable of the long series of philanthropic acts on the part of this distinguished Hindoo on a scale of magnificence hardly ever equalled.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM JANUARY 24 TO JANUARY 30, 1888.

BURTON, H. G., *Captain and Assistant Surgeon.*—Granted leave of absence for one year on S. C. D., to take effect when able to travel.—*S. O.* 19, *A. G. O.*, January 24, 1888.

FISHER, W. W. R., *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for one month, on surgeon's certificate of disability.—*S. O.* 4, *Department of California*, January 20, 1888

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING JANUARY 28, 1888.

WHEELER, W. A., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, January 24, 1888.

WHITE, J. H., *Passed Assistant Surgeon.*—Granted leave of absence for two days, January 26, 1888.

WATKINS, R. B., *Assistant Surgeon.*—Granted leave of absence for thirty days, January 28, 1888. Resignation accepted to take effect March 15, 1888, January 28, 1888.

VAUGHAN, G. T., *Assistant Surgeon.*—Appointed an Assistant Surgeon January 25, 1888, vice A. D. Bevan, resigned. Assigned to temporary duty at Marine Hospital, Boston, Mass., January 26, 1888.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LII. SATURDAY, FEBRUARY 11, 1888. No. 6.

ORIGINAL LECTURES.

THE ANNIVERSARY ADDRESS

Before the Medical Society of the State of New York.

Delivered at Albany, February 8, 1888.

BY ALFRED L. LOOMIS, M.D.,
PRESIDENT.

GENTLEMEN: I desire this evening to invite attention to the following problems which are to-day engaging the attention of the profession, and for which it is asking solutions:

1st. The relation of microbes to disease processes.

2d. Inoculation as a means of modifying or preventing disease.

3d. The causes of abnormal temperature in disease.

4th. The effects of antipyretics in the treatment of disease.

Every generation of medical workers has had its special theories and supposed discoveries, to test, to accept, or discard; but never before has the field of medical investigation been so extensive, the workers so many and able, and the methods of research so varied.

It may be interesting as well as instructive, by way of introduction, to sketch briefly some of the methods of investigations which in different ages have held the profession, and compare them with the methods of to-day. Before instituting any comparison, however, it is but just to recognize that all knowledge is of slow growth, and that the law of development applies to mind as well as to matter—we condemn methods and means, because they have been tried and found wanting, and not because of personal superiority of intellect—nineteenth century intellectuality must own its indebtedness to mistakes and failures which antedate the birth of Christ.

In every science results are reliable and valuable in direct ratio, not only to the accuracy with which deductions are made from given data, but also to the methods of reasoning, the truthfulness of postulates, or supposed facts, and the recognition of all the relations which may exist among determined facts under varying conditions.

No one can deny to the father of medicine equal ability with himself, even while criticising and condemning many of his arguments based upon well observed facts. He argued from but a few of the many correlated symptoms of any disease, in entire ignorance of all its primary pathological changes, and erected a system of medicine on the basis of his own observation. The earlier periods of medical history present themselves as curiosities rather than times which we may fairly criticise or compare with our own—medical investigation so superficial could hardly lay claim to the name of method—with but little anatomical and no pathological knowledge it is hardly to be wondered at that even the best minds were lost in the wildest forms of speculation.

We recognize most clearly that no one mind alone can advance medical knowledge, but by an infinitesimal degree, and even this is the result of a mutual interchange of thought. In ages then when strong minds were few and intercourse most limited, men must needs have been more than human to have accomplished more than the masters did. But ambition outran ability, for long before "ye men of Athens spent their days in hearing and telling some new thing," the same search for ultimate facts had been going on, and human minds impatient of meagre results gained through the hard logic of facts, easily drifted into the limitless sea of theory and quickly lost sight of the land of truth and possibility. To speak more exactly, the deductions of theories from few and isolated facts and the construction of entire systems of medicine upon a single and often unproved assumption is characteristic of the earlier ages of medicine. By how much is the medical mind different to-day; under greater restraints, by reason of sharper criticisms, and with broader foundations no such extensive speculative theories are offered for our consideration as mark the earlier history of medicine, but the same spirit remains as one of the heaviest clogs to the advancement of true medical knowledge.

When theoretical conclusions are put forth as established facts, and not as questions demanding experimental answers, then modern medicine is not only turning back to the darkness of earlier ages, but it is putting a stumbling block for the feet of those who follow.

There is no better test of the scientific mind than its power in deciding, after any given demonstration, between legitimate corollary and unfounded inference.

In no direction perhaps has medicine made greater advances in the last quarter of a century than in this; give us facts not fancies—proofs, not propositions, is the demand of the medical mind of to-day—"it is digested facts which nourish thought," not crude ones.

The empiricism of the Alexandrian school is perhaps the earliest system of medicine founded on a scientific basis, and offers the fairest points for comparison with the scientific empiricism of to-day. In this school anatomical and physiological investigations were recognized as essential to a thorough knowledge of disease. There was, however, a marked failure to recognize the necessity of determining the changes that were produced in organs and tissues by disease, and to connect morbid conditions with symptoms. Histological pathology was an impossibility without instruments of greater precision, and even gross pathology received no attention. Such a failure to appreciate the evident results of pathological processes is the more remarkable in a school which did more than all others of ancient times to advance medical knowledge.

Under the shadows of the granite hills of New Hampshire, on the banks of the Connecticut, the last resting place of one of the fathers of New England medicine is marked by a small white stone having only this inscription, "The Disciple of no Man." It is not alone the

description of that man, it is the keynote of modern medicine, and symbolizes one of the grandest changes which has ever revolutionized any science.

For nearly a thousand years the history of medicine may be traced by a few names. Schools were founded on men, not principles, until loyalty to one's master, the founder of a school, was stronger than loyalty to truth; and it was doubtless better, both for medical science and the patient, that the multitude were content to be led, and that between masters and pupils such relations should have existed. But that such a condition of affairs should have continued so long after the "period of letters" in Europe, is a cause for astonishment. Even as late as the sixteenth century, Galen and Aristotle, and the Arabic authorities, were the teachers of medicine throughout the civilized world.

When Ambrose Paré, defying the traditions of more than ten centuries, and the teachings of all authorities, took the bold step of tying an artery, he became the embodiment of that individuality and scientific scepticism which to-day are among the most striking characteristics of medical men—an individuality which thinks and decides for itself, a scepticism which doubts, not for the sake of doubting, but because it has too often leaned on broken reeds, too often placed its trust in authority only to find it like apples of Sodom. A scepticism which demands proofs and counter-proofs; which scans facts, not men, and learns to recognize truth whether offered from the wilds of the new world or the literary storehouses of the old. As a legitimate result of this spirit there has been developed, what is without question the greatest advance in methods ever made in medical science. It is the step which has made medicine truly scientific. From the crumbling ruins of abstruse theories and the wrecks of individual systems, overthrown by honest scepticism, comes the recognition of the fact that man is not an accident of undetermined forces—the one thing in all the grand scale from worlds to worms that is without plan, or subject to law—but rather the crowning glory of infinite wisdom, a machine of marvellous intricacy, yet subject to and obeying the laws of his being, with the same certainty as the sun holds his attendant planets in their unchanging way; and what has been the result? The medical world has started afresh at the very rudiments of the science. It has taken its primer, and in the kindergarten of the laboratory, it is seeking to know the laws of life and health, and the causes of disease. It has gone far beyond what antiquity ever dreamed. It has developed the empiricism of the Alexandrians, and curbed the philosophy of the Greek. It is seeking to unite scientific empiricism, with equally scientific theory, into one perfect whole; to have all theories based upon clearly determined facts, and to use such theories only as guides to the discovery of the next link in the chain which shall some day bind in eternal subjection the bacillus that walketh by day, and the coccus that rageth by night. When the medical history of the nineteenth century shall be written, it will be that of the laboratory, and the names which the twentieth century will honor, are the names of those who have devoted their lives to establishing the unchanging laws of both health and disease which govern this infinitely complex machine which Infinite power has made in His own image.

Our first problem for discussion is

THE RELATION OF MICROBES TO DISEASE PROCESSES.

In looking over the field of bacteriological research for the past ten years, one is struck by the continuous, painstaking investigation of a vast number of observers. Never before has there been so little theorizing, with so much work, and the facts which have finally been accepted are such as have come to light only after a long series of carefully made and oft-repeated experiments. One investigator makes a statement, immediately, in a dozen different countries, and by hundreds of observers, his experiments are repeated; his statement of facts proved or disproved, and his conclusions accepted or discarded. The results which have been reached in so short a period prove the wisdom of Agassiz's principle, "That science suffers by every diversion of the energy of scientists, which tends to substitute premature theorizing for continuous investigation."

It is not my purpose to consider the biology of the different varieties of the bacteria—the conditions of their life—their susceptibility to be influenced by temperature—by the different media in which they grow, nor yet in turn how they act and react upon each other, and upon the substances which have nourished them. It must suffice merely to touch upon the practical questions presented by such studies. The life history of some forms of bacteria has been very thoroughly worked out, but the majority have been as yet imperfectly studied. On account of their universality and their peculiar vital properties, the question which most interests us as practising physicians is, May not these microbes have the power of originating and controlling many of the morbid processes which take place in disease? When we consider the millions of microbes by which we are constantly surrounded—that the soil beneath us and the air around us is laden with them—that they enter the body in the very air we breathe, the food we eat, the water we drink, and yet, their influence is baneful only under certain conditions; that it is even possible for men to live in an atmosphere and surroundings which are ladened with the most pernicious forms of bacterial life, and yet be perfectly well, the question comes to us, Why is this? If this question is ever answered, it will not be until we have a fuller knowledge of the conditions of life, and the inherent properties of even the most carefully studied varieties of bacterial life; nor until we are able to trace more fully the cause and manner of their disappearance after they have gained an entrance into the healthy organism which is able to resist their invasion. It may be regarded as demonstrated that when certain pathogenic microbes have gained entrance into the body and reached localities which afford certain conditions for their development they multiply and form colonies, but what these conditions are is not definitely determined. For example, if a mass containing different varieties of bacteria is introduced into an animal, some will find a suitable soil and multiply, others will die—while if a similar mass is introduced into an animal of a different species, those bacteria which develop in the first animal will perish in the second—as the bacterial colonies enlarge or multiply they invade the surrounding tissue cells, and in time produce degeneration and necrosis of the affected part; as a result of the disturbance of the circulation, the walls of the bloodvessels are weakened and the microbes gain entrance to the blood current. In a similar manner the

lymphatics are invaded. If the blood or lymph offers conditions suitable for their growth they multiply rapidly, otherwise they perish—their death is supposed by some to be due to the special action of the white corpuscles. Some bacteria flourish best in blood which is flowing, as the bacillus anthrax—others, as the tubercle bacillus, in blood at rest, and still others only multiply rapidly in the lymph, as the micrococcus of erysipelas. Conveyed by blood or lymph the bacteria lodge in different organs and there start secondary changes, similar to those which have taken place at the primary seat of invasion—this is well illustrated in animals that have been inoculated with pure cultures of tubercle. In this connection three questions naturally present themselves:

1st. Are organisms present in all morbid processes?

2d. Can they originate *de novo*—and is there a mutability of the bacteria?

3d. And by far the most important question: Do microbes act as invariable and sole causes of disease? Or are they the result of pathological processes instituted in their absence?

In answer to the first question, *Are organisms present in all morbid processes?* it may be stated that it is to-day claimed that specific microörganisms have been demonstrated in the following diseases—splenic fever, relapsing fever, erysipelas, tuberculosis, cholera, pneumonia, malarial fevers, smallpox, scarlet fever, measles, diphtheria, typhoid and typhus fevers, pyæmia, leprosy, acute rheumatism, ulcerative endocarditis, pyelitis, gonorrhœa, acute atrophy of the liver, and in a number of skin diseases, as herpes, sycosis, etc. And it is claimed that our inability to discover them in other diseases is no proof of their absence, for their minute size, and peculiar reaction to staining agents, render their demonstration very difficult, and as yet we have no general method by which we are able to recognize the spores of these organisms, which are known to be more resistant than the microörganisms themselves. Again, our examinations may be made in the advanced stage of the disease processes, when all traces of bacteria may have disappeared, for it has been shown by experiments upon animals, that by the time that tissue changes occasioned by bacteria are complete, they themselves have disappeared—not until our technique is more perfect can we say positively that bacteria may not be found in all diseases, especially infectious and contagious ones.

In answer to the question, *Can bacteria originate de novo, and is there a mutability of the bacteria?* it may be stated that no reliable evidence has as yet been deduced to show that microbes can originate spontaneously. The experiments of Lister and Pasteur prove almost conclusively that it is impossible for them to originate spontaneously. Koch, from his culture experiments, concludes that one form of bacteria cannot change into another form, that micrococci can never become bacilli; nor can the innocuous varieties by any change in the conditions of their lives become noxious; although many observers, such as Nagel, Davine, and Buchues dispute this; still, at the present time, the weight of evidence is with Koch. There is no doubt that the properties possessed by different bacteria may be modified, increased, or diminished, by changes in their external conditions; at one time they are more infectious than at another, but never do they acquire attributes differing from those possessed by the variety to which they belong; even in bacteria there is a struggle for existence, the micrococci may be thrust aside by the bacilli.

Our third question is more difficult to answer than either of the others, viz., *Are microbes the cause or effects of disease?* If they can be proved to be the cause, then their presence is of the greatest importance; while, if they are only the effect, our interest in them from a medical standpoint ceases. What then is the precise significance of their coexistence with the diseased processes? The facts which seem to be established at the present time are as follows: Pasteur having proved by his vital theory that bacteria are the cause of all fermentation and putrefaction, students in, and believers of, the germ theory of disease, noticing the close relation these fermentative and putrefactive processes bear to communicable diseases, reasoned by analogy, that they likewise must be of bacterial origin. After carrying on a long series of experiments; such as inoculating animals with pure cultures of various species of bacteria, it was demonstrated that in some of the specific diseases bacteria are developed, and that the same microörganism is always present in the same disease, and that these organisms could be transferred from animal to animal without changing their characteristic form—their specific physiological action—and without the presence at any time of any other form of bacteria. Therefore it was inferred that not only are these diseases of bacterial origin, but that each disease is developed only from its own microorganism, recognizable under the microscope by their size and shape, their staining properties, peculiarities of growth in nutrient media; and, as has recently been demonstrated, by their chemical reaction; for example, during the past year Koch has shown that the Finkler bacillus, the comma bacillus of cholera nostras, which is considered by many as identical with his comma bacillus of Asiatic cholera, can be differentiated from it, not by its size and shape, but by its reaction to nitric acid; for by adding nitric acid to a growth of the cholera bacillus, a very characteristic red color is produced, while no reaction whatever is shown on the culture of the Finkler bacillus. Thus advances are being made every day, which lessen the elements of uncertainty. In this connection it must be noted that we do not as yet know why different animals behave so differently toward infectious agents, still less can we account for differences in their susceptibility, for an experimenter soon learns that there is a marked difference among the lower animals, as to the degree and manner in which they are affected by microbes. One form will flourish in one species and not in another; rats are unaffected by the anthrax bacillus, while mice readily succumb to their invasions. Even among animals of the same species, there is a marked difference of susceptibility to the infectious diseases, and most of the animals upon which experiments have been made are subject to but few of the diseases of man; the power of resisting inoculation is evidently far less in animals than in man; it is, therefore, reasoning from false premises to say that the action of microbes upon animals is the same as upon man.

While a reasonable conjecture may be reached regarding the bacterial origin of infectious diseases by our experiments upon animals, positive proof can be obtained only by studying the action of their microbes upon the human body. The only diseases in which a bacterial origin has been completely demonstrated in man, are

erysipelas, splenic and relapsing fever. The proof that the tubercle bacillus is the cause of tuberculosis, requires yet the crucial test of human inoculation. The explanation of the action of bacteria in disease, as given by Prof. Ziegler, seems to me the most comprehensive and satisfactory which has yet been given. He says: "The factors which determine the invasion and the course of the development of bacteria within the human body are two.

"1st. The bacteria must be endowed with certain vital properties of a special kind.

"2d. There must be a certain predisposition to favor their development on the part of the system." For example, one with no phthisical predisposition, either inherited or acquired, may live in an atmosphere laden with tubercle bacilli, and never develop phthisis, while one with strong phthisical predisposition, under the same conditions, furnishes a fit soil for the growth of the bacilli, and quickly succumbs to their invasion. This factor of predisposition is the important one in the problem. What it really consists in, is as yet undetermined; probably it is due to some alteration of the tissues, often we can see what this alteration is, such as a local wound, a disturbance of the circulation, etc., but in the majority of instances the anatomical basis of this change is an unknown quantity which is yet to be worked out. When found, then the cycle of proof will be complete; the simple demonstration of the presence of the tubercle bacilli in phthisical processes and in the sputum, is of great practical value in the early diagnosis of phthisis, but it does not determine the relationship that exists between the bacillus and the phthisical processes. We must not lose sight of the possibility, that it is only after the physico-chemical constituents of the tissues have been morbidly altered, by a yet unknown agent, that the conditions are such as to allow of the growth and colonization of the different pathogenic microbes. If in time it shall be conclusively proved that microbes alone, or microbes plus some, as yet, unknown quantity, are the cause of disease processes, we can readily appreciate the great importance of the knowledge which is to-day being gained by bacteriological studies, and we may hope in the near future to be able to discover the microbes of each disease, and to destroy them, or render them harmless, and so combat early the development of many diseases that at present we are unable to control.

I will now pass to the consideration of our next problem, viz.:

INOCULATION AS A MEANS OF MODIFYING OR PREVENTING DISEASE.

This problem has been strongly brought before the profession by Pasteur's recent experiments in hydrophobia. The protection afforded by vaccination, against smallpox, not only by granting immunity from the disease, but by modifying its severity when it is developed, brought first before the world the practical advantages of inoculation. The next great discovery in this direction was made by Pasteur, who found that by the prolonged culture of the anthrax bacillus at a temperature of 107.6° F. or 109.4° F., and with exposure to the oxygen of the air, the virulence of the organisms decreased. Animals inoculated with the attenuated virus developed only a mild type of splenic fever, and after recovery were found to be incapable of again developing the disease even when inoculated with virus of full strength. After repeated inoculations with attenuated virus, Pasteur found that inoculated sheep were quite unaffected by injections of a pure culture of the bacillus. A practical application of this discovery has since been made by agriculturists throughout Europe. Toussant, by cultivating the bacteria of chicken cholera, found that each successive generation was less virulent than the preceding, and that this attenuated virus when introduced into animals produced a severe local lesion with but slight constitutional disturbance, and that after recovery the inoculated animals were exempt from the infection for a year or more, after which time a second inoculation was necessary. More recently Koch has proved the immunity afforded by inoculation in another disease known as the septicæmia of mice. If a rabbit be inoculated with septicæmic blood, it will die within seventy hours, but if a weakened culture of the septicæmic bacteria be introduced into the tip of a rabbit's ear the animal will only suffer from the local effects of the virus, and afterward will not be affected by repeated inoculation of the strongest culture. Koch also showed that such immunity could not be conferred by inoculation with attenuated virus in all infectious diseases—for instance, relapsing fever can be produced again and again in the same animals after inoculations. Experimenters more recently, from these and other results obtained by inoculating animals with attenuated bacteria of different infectious diseases, have sought to furnish proof that similar inoculations in man would be followed by similar immunities.

The fact that individuals who have once passed through certain infectious diseases, or a mitigated form of them, are afterward not susceptible to the infection of these diseases, may be regarded as a strong evidence of the possibilities of such immunities being obtained by inoculation of the attenuated viruses of infectious diseases. While working in this line Pasteur brought forward the results of his inoculations against hydrophobia. Both his experiments and his results have aroused adverse criticism from those whose ignorance of the subject forbade any fair discussion of his methods or conclusions, as well as by those who presumably were competent to sit in judgment upon him; as a consequence the profession has been slow to accept his conclusions.

It would seem, however, that the report of the English Commission appointed by Parliament to investigate the subject, composed as it was of the best English observers, must at once put at rest all doubts. This report is all the more interesting and valuable because it is the first that has been made by impartial and competent authority upon Pasteur's work. The report of the Commission declares that it is certain that Pasteur has discovered a method of protection against hydrophobia comparable to that given by vaccination against smallpox; and in their opinion it is "difficult to overestimate the importance of the discovery," and that while not every case which he has treated has escaped, yet a large proportion of cases have been absolutely cured. The report of such a Commission will not only give to Pasteur's researches and experiments an authority which they have not before had, but it will also give an impetus to similar investigations in other directions, for a method of inoculation is presented by his experiments by which it may be possible to prevent other diseases in man. The diseases which up to the present time have been proven to be prevent-

able by inoculation, are vaccinia, variola, splenic fever, and if we regard the report of the English Commission conclusive, hydrophobia.

All the explanations that have been given of the immunity afforded by inoculation are unsatisfactory and at best only conjectural. It seems possible that a person who survives an infectious disease has in his struggle with it acquired the power of resisting such infection by some as yet unknown modification in the chemical constituents of his tissues, and that acquired immunity from inoculation is on the basis of the introduction of an infection in minute quantities until such a chemical change has been reached; but all such explanations are only suggestive, while it has been proven that inoculation is protection in a few diseases, it is reasonable to infer that those diseases in which one attack is protection against a second, that preventive inoculation is possible, and it opens a wide field for investigation and experimentation.

THE CAUSES OF ABNORMAL TEMPERATURE IN DISEASE,

is the third problem to which I invite attention. What is fever? is a question that still remains unanswered, and which is constantly pressing itself upon the clinical observer for solution. Few subjects have been more at the mercy of theorists, or been made more the sport of ingenious minds. In discussing it we are primarily led to a consideration of the animal heat of normal conditions. It is comparatively easy to reach reasonable and, indeed, demonstrable conclusions on the physiology of this subject up to a certain point. Beyond this we are confronted with difficulties which, with our present means, we are unable to solve with any approach to success or satisfaction. In regard to the causation of a certain amount of manifest energy, in the form of heat, as exhibited in the body of animals, there appears to be no reasonable objection to the view that conditions which result in the manifestation of such energy outside the body shall exhibit similar calorific effects within the tissues. It is well established that foods exhibit their heat potential in the changes incident to the production of water and carbon dioxide, and these demonstrations of chemical force are true combustions, and yield stored heat just as certainly as when like changes occur apart from the living tissues.

In the light of present physiology it appears almost self-evident that the prominent factor of heat production exists in metabolism, and that metabolic processes consist in the liberation of heat stored in the food introduced into the body. The inadequacy of these changes alone to account for the maintenance of an equable temperature of the body during the extraordinary and varying conditions of man's environment also seems apparent.

Very early in the investigation of this subject one becomes conscious of the imperative necessity for the existence of some regulating mechanism. I must, however, say just here, that I have never been able to convince myself, from analogy or otherwise, of the necessity for a nervous mechanism which shall give rise to heat-production without corresponding chemical changes either general or local. Such a theory to my mind calls for effects without a cause. I cannot, in other words, conceive of any reasonable evidence against the view that physical processes must be governed by the same laws and be productive of the same results, in every instance and under all conditions.

This brings us squarely to the question, Is the hyperpyrexia of fever an extraordinary manifestation of animal heat, governed and controlled always by the same mechanisms, differing only in degree? Or, are the conditions other than those of simple pyrexia, requiring special mechanisms for its development? In the study of the literature of this subject we find that increased calorific manifestation resulting from an exaggerated body metabolism was, for a long period, deemed a reasonable explanation of the temperature of fever. This view was based upon the fact that food and tissues represent a certain and definite potential, that in the metabolic processes this is exhibited as kinetic energy in the form of heat. Later these changes were found to be under certain nervous control, and special mechanisms were demonstrated as regulating metabolism without offering any objection to the combustion theory of animal heat and of fever as well; within a comparatively recent period the theory has been advanced that pyrexia results from a disturbance of the normal equilibrium between the production and dissipation of heat.

The views advanced by Maclagan and others on this subject are essentially as follows: 1st. That in the ordinary production of animal heat, the influence of the nervous system is neither essential nor exhibited, even though the pyrexia be considerable. 2d. That as soon as the disturbance induced by fever occurs, or the normal balance between heat production and heat dissipation is reached, nervous mechanisms are called into requisition and hyperpyrexia results. 3d. That the contagium of fever consumes the proteids designed for tissue repair.

It has been pretty conclusively shown by the experiments of Dr. Wood that an inhibitory control—a check—is in constant supervision over ordinary heat production, and he has located with more or less definiteness a cerebral heat centre, the normal inhibitory action of which is reflexly withdrawn in fever, and the resulting increased metabolism is exhibited in increased temperature. Dr. Wood has performed many carefully conducted experiments on animals in the settlement of the question: "Does fever consist in an increase of heat dissipation from the body or in an increased heat production?" It is difficult to understand just how the body can continue to dissipate heat for any prolonged period without a corresponding heat production.

Thus far experimental physiology has proved an efficient help in determining the mechanism of fever, but all attempts to isolate the spirit which primarily actuates these mechanisms have left us groping for an agency which we have thus far found too subtle for recognition.

What causes the peripheral stimulus which Dr. Ordt and others believe is carried to the spinal thermogenetic centres and there translated into influences which are transmitted to the tissues, to increase or diminish those transformations upon which depends the amount of heat produced? What is this morbific principle which so influences the cerebro-spinal centres of Brodie, Hitzig, Eulenburg, Landois, Wood, and others, as to inhibit their action on the heat reservoirs of the tissues by increasing chemical metamorphosis? Such questions as these force us back to the original proposition—What is fever? One must plainly see the futility of attempts to answer this question until some more satisfactory definition can be given, than that fever is an exhibition of phenomena or symptoms of which high temperature is the most prominent. Fever is a something which we have not yet

grasped; which produces those symptoms or *effects* which we have been accustomed to regard as its *cause*. Beyond this we actually know nothing, except that the result of its presence is manifested largely, at least, through the nervous apparatus; and knowing so little of its nature its causes must be speculative. What is destined to come out of the work in the direction in which the medical world is now active remains to be seen.

The establishment of a special nervous control over heat production will unquestionably remain an important and leading idea in the physiology of pyrexia at least. The disposition evinced by various observers to regard the febrile conditions as produced by a specific cause—one entirely distinct and apart from normal phenomena—has not as yet modified in any very essential degree the views entertained by clinicians of the earlier part of the present century. Unsatisfactory and incapable as the chemical theory is in accounting for certain temperature manifestations, it must remain the leading and influencing thought on this subject, until something essentially and radically different from that afforded by the results of present experimenters has been suggested.

We may sum up our knowledge on this subject as follows:

1. Chemical transformations produce definite results, whether occurring within the tissues or outside the body.

2. The body takes cognizance of the potential of food, and during certain changes, which are true combustions, a definite, unalterable value is exhibited as kinetic energy in the form of heat.

3. Muscular action is an insignificant factor in the establishment of animal heat, excepting as it excites metabolic energy.

4. The varying circumstances of man's environment necessitate some heat-regulating mechanism to preserve the conditions of homogenesis.

5. The evidence of the existence of a regulating mechanism operating independently of chemical change is insufficient.

6. There appears to be no reason for regarding the increased heat-production of fever as requiring mechanisms other than those acting in normal rise of temperature.

7. While anatomical difficulties interfere with the complete isolation of such ganglia, the existence of two cerebral inhibiting heat mechanisms has been fairly established; as much may be said of like spinal ganglia.

8. The production of heat in fever is in exact consonance with metabolism and the chemical changes are under the control of the heat mechanisms through the connection between the nervous and the vascular apparatus.

9. In the present state of our knowledge we can only theorize as to the identity of the material in the circulating media of the body, which institutes the primary irritation in febrile conditions. That it is inconstant in composition or nature, there is abundant reason for believing. That it is microbic in every instance, I am unprepared to admit. We certainly must have a clearer idea of what fever is before we accept or seek to explore the action of poisons or microbes in producing it. We are too prone to seek for the causes of phenomena before we have determined the precise nature of the phenomena themselves. It is evident that the bacterial pathology which is dominating all the teachings and investigations of the present day, has as yet, given us no clew to an explanation of the causes and phenomena of fever.

The length of time already occupied in this discussion will compel me to be brief in my consideration of our last problem, viz.:

THE EFFECTS OF ANTIPYRETICS IN THE TREATMENT OF DISEASE.

During the last decade, since the thermometer has become a part of the physician's "armamentarium," antipyretics have taken a more prominent place in the treatment of disease than ever before, probably for the reason that by it we are able more readily and accurately to determine their effects upon the body temperature. If we accept the view that high temperatures cause destructive metamorphosis of tissue, a view which in some unaccountable way has gained almost universal acceptance—the importance of reducing high body temperatures in all diseases cannot be overestimated, and we are justified in resorting to the most powerful antipyretic agents to accomplish it. But there is very little, if any, evidence that febrile temperatures of 106° or 107° cause any serious injury to the body; certainly that no such dangerous destructive changes take place in the blood and solid organs as we have been led to suppose from the writings of continental observers. I can find no clinical or experimental evidence to sustain the popular doctrine of Liebermeister and others, that the grave symptoms in fever, the symptoms which usually render a prognosis unfavorable, are referable to a high temperature range. In fact, the evidence of the so-called parenchymatous changes and of the grave febrile symptoms in acute infectious diseases, are as well marked and as often present in cases where the temperature-range at no time reaches 103°, as in those cases which are attended by very high temperatures. In a series of cases of typhoid fever of low temperature, often subnormal, which have come under my observation during the past year, in which the ratio of *mortality* was unusually high, I was surprised at the development of so many of those very grave symptoms which I have been accustomed to regard as due to the effects of high ranges of temperature; from these, and similar observations in other acute diseases, I have come to the opinion that there is no necessary relationship between the other febrile symptoms and the temperature range.

It is evident that we have passed through the period of enthusiasm in the antipyretic treatment of disease, and already prominent workers have come seriously to consider whether the dangers of hyperpyrexia have not been over-estimated, and the question is being asked, May not the high temperature in disease, especially in infectious diseases, be a conservative process. From statements already made, it is evident that elevation of temperature is far from being all that there is to fever.

A pertinent question for every practitioner of medicine to put to himself is, How much has he accomplished by the use of antipyretics, in the arrest and safer conduct of disease, and are there no dangers attending their employment? Whatever answer may be given to these questions, I am convinced that the heroic use of antipyretic measures which within the past few years has come into such general use—the one idea of the modern therapeutist being to reduce temperature at all hazards—has a side of danger that should not be lost sight of. If the temperature range in a case of fever or pneumonia is about

105° or 106°, and can readily be reduced by mild antipyretic measures, the condition of the patient at the same time being made more comfortable by their use, I should most certainly recommend their employment. But when powerful antipyretic measures are required to effect temperature reduction, and its reduction is only temporary, I question very much their beneficial effects; in fact, I am quite confident that such reductions are obtained only by an expenditure of vital force on the part of the patient, which largely diminishes his chances of ultimate recovery, especially if the hyperpyrexia has been long continued, for I have frequently noticed that their daily employment, for a prolonged period, has been followed by grave nervous phenomena, and the evidence of the most extreme cardiac failure, greater than could have been caused by the high temperature alone. I think no one whose experience is at all extensive in the use of antipyretics in the treatment of acute infectious diseases, will for a moment claim that they have any power in shortening their duration or greatly modifying their severity.

Time will not allow me to enter into a detailed account of the different antipyretics now in use, to compare their relative merits, nor to theorize as to their mode of action. In a general way they may be divided into two classes, the application of cold to the surface and the internal administration of antipyretic drugs. The mode of action of the two classes is evidently not the same, although they both may effect the reduction of temperature. Whether they act by diminishing heat production, or by increasing heat dissipation, is still undetermined; for every day's experience teaches that sometimes when antipyretic drugs act badly or inefficiently, cold applied to the surface in the form of baths or packs, often accomplishes the desired results in the most satisfactory way, and *vice versâ*. It has seemed to me that the beneficial action of antipyrin and antifebrin is not so much due to their power of controlling temperature, as to their tranquillizing effects upon the nervous system. Dr. Wood, from his experiments on animals, concludes that antipyrin diminishes heat production and heat dissipation, and that its action on the bodily heat is entirely independent of any influence on the circulation; that it probably acts through the nervous system directly upon the chemical movements of the organism.

Clinical experience has taught me that opium is often one of our most efficient and reliable antipyretics. The old custom of administering Dover's powder in small doses, at stated intervals, throughout the course of a typhoid fever, undoubtedly had its origin in the power of opium to control temperature by its tranquillizing effects upon the nervous system, as all discussions in this line must at present be theoretical and unsatisfactory. I close the consideration of this problem, with the practical question: If temperature reduction does not shorten the duration, mitigate the severity, or avert serious complication in disease; and if the ratio of mortality is not so diminished as to encourage us that we are making advances by antipyretic measures, on *what basis are we justified in their use?* Evidently, only on the basis that by their use we relieve one of the many phenomena of fever. If this can be accomplished without serious loss of vitality, or at the expense of the reserve force of the patient, we are justified in their use; but do not let us imagine that by reducing temperature we are controlling fever.

In review of the subjects which I have brought to your notice this evening, it is evident that the work of to-day is gradually rescuing medicine from the realm of wilful and unreasonable speculation, and is establishing it on a basis of new facts. Yet I would warn those who are in haste to elevate the experimental above the practical, that the experimental will never alone be able to accomplish the great work that is ever before the practical physician. We cannot safely forsake the rich storehouse of clinical observations that have been gathered by so many master minds, and withdraw into the recesses of the laboratory; for, although in the work of the laboratory we hope to find the solution of many of the problems with which we are now struggling, it must be remembered that the special field of medical investigation is, and ever will be, the study of disease in its activities. Experimental work, even in the study of the causes of disease, must always be onesided, the whole number of its causes can only be studied and understood at the bedside of the patient. The great treasures of clinical observations must ever be the basis of true medical advancement. It is here that medicine is to find her firm and enduring foundations. Let us then labor without rest, in the laboratory, at the bedside, and in the deadhouse, for the solution of the great and vital problems that are before us in every branch of our science, and the full benefit of our labors later generations will come to know and enjoy.

ORIGINAL ARTICLES.

SÄNGER-CÆSAREAN OPERATION NECESSITATED BY A PECULIAR CAUSE AND ACCOMPANIED BY UNUSUAL COMPLICATIONS.

BY R. B. NORMENT, M.D.,
OF HAMPDEN, MD.

ON the 16th of December, 1887, I was called to see S. C. M., aged twenty-six, white, unmarried, who was at that time eight months pregnant. She was troubled with violent headache and a hacking cough, on account of the former of which, she consulted me. The patient was a small hump-backed woman, who had been afflicted with Pott's disease of the spine since early childhood; and she told me that she still had many sores on her back. The deformity of the patient presented itself to my mind as rather remarkable, in that when she was standing, the ensiform cartilage and pubes were nearly on a level.

A careful examination made on the 18th revealed the following facts: Patient is 49 inches high, and very thin; there is marked kyphosis the result of Pott's disease, involving the entire dorsal region (indeed it seems to me that the entire spinal column below the vertebra prominens is involved); the lower ribs are in the upper pelvis; the uterus hangs pendulous over the pubes; the symphysis lies a little posterior to the femurs when the patient is standing; the vulvar opening looks slightly backward; there is marked contraction at the lower strait, the distance between coccyx and pubes being about two inches, but I fail to discover any contraction in the upper strait: the ensiform cartilage is much too near the pubes, the distance between the two being estimated at 6 to 6½ inches (in reality it was something less;

measurement after delivery showing it to be but 5¾ inches).

These facts led me to fear that I would have great and serious difficulty in delivering my patient when the time of her labor had arrived. The position of the uterus was what presented itself to my mind as the greatest difficulty I would be called upon to combat, hanging pendulous when the woman was standing, the fundus uteri being in a plane eight and a half inches below the tip of the coccyx, lying between her thighs when she assumed the recumbent posture. There was no room to lift up this anteverted uterus, for the sternum was far anterior to the pubes; the patient being in a recumbent position, a line drawn from the pubes to the sternum would have made an angle of about fifty degrees with the horizontal plane.

The case presented itself to me in this light: In order to accomplish delivery *per vias naturales*, it will be necessary to make the entire body of the fœtus describe an arc of a circle equal to 270 degrees or thereabout. As there was contraction at the inferior strait sufficient in my judgment to necessitate perforation or crushing of the fœtal head, I thought the hope of accomplishing this would be infinitely small.

After deliberating over the matter for a day or two, during which time the patient was being treated for her headache and cough, I concluded that it would be best to prepare the patient and her family for the Cæsarean operation.

The general condition of the patient was about as bad as could well be imagined. In addition to the great deformity above mentioned, I found the lower extremities œdematous from the toes to the hips; the urine highly albuminous, and containing *hyaline* and *fatty* casts in large numbers. There were two open suppurating sinuses in the lumbar region, one just below the anterior superior spinous process of the left ilium, and one in the anterior surface of the right thigh about six inches below the hip-joint. The patient could not say just how long *these* had been discharging, but there had not been a time during a space of more than twenty years when she was free from the discharge of pus from a sinus *somewhere*.

There was one very curious circumstance noticed at the examination. When the finger was passed into the vagina, it seemed that in whatever way it was directed it came in contact with a bowel filled with feces. I am of the opinion that the sigmoid flexure of the colon was in the pelvis. The patient was ordered free purgation with salines, as well as frequent enemata. For medicine she took iron, quinine, and bromides in various combinations. By these measures she was rendered more comfortable for about twenty days, when symptoms of uræmia set in, headache, dizziness, blindness, tremor, and nervous twitchings and great restlessness during sleep; limbs more œdematous than ever; urine scanty, albumen and casts abundant. Eclampsia seemed imminent. She was ordered large doses of pulv. jalap comp. (℈j every three hours) until violent purgation ensued. Potassium bromide was freely administered, and patient kept for a few days upon a liquid diet. When she had been very freely purged the symptoms ameliorated to a marked degree, and I ordered tinct. ferri. et ammon. acetat. ʒj every three hours, and potass. brom. ℈j at bedtime and as often during the day as might be required in order to keep her headache in abeyance. Her condition again improved.

In the meantime all things were prepared for the operation whenever emergency might demand. The family and patient were plainly told the seriousness of the situation as well as the dangers of operative procedure. To the former no hope of the patient's recovery was held out. I did not, however, deem it wise to tell the patient that I thought it absolutely impossible for her to recover, though I plainly made known to her the *danger* she was called upon to encounter. The patient and her family readily gave their consent to any operation which might be deemed advisable.

I visited my patient daily from the time I was first called to the time of operation. At my visit, January 12, I was informed that she had had some pain simulating that of labor during the previous night, but there had been no return of the same for twelve hours. There was no further return of pain during that day or the following night, but at four P. M. on the 13th, regular dilating pain set in. Having lasted for upward of two hours, I was sent for, and found the cervix slightly dilated and soft; the patient, however, was suffering little pain. I was informed that her pains had been regular and frequent, "real down hard pain," until she was told that I was coming, when she became nervous, and the pains ceased for some time.

In consideration of the fact that the patient was very weak, that she had already suffered pain for three hours, that, should her labor occur later in the night, the difficulty of securing assistants would be greatly increased, I determined to operate as soon as assistants could be procured, and the patient prepared for the operation.

The pubes were shaved, the abdomen washed thoroughly with soap and water, and covered with a towel, wet with a solution of hydrarg. bichlor., 1 : 2000. The sinus under the iliac spine was washed out with the bichloride solution, and plugged with absorbent cotton, and a fold of linen wrung from the bichloride was placed in the groin; that in the thigh was treated in the same manner, except that it was covered with a piece of India-rubber plaster. The bladder and rectum were emptied, and the vagina washed out with a two per cent. solution of carbolic acid.

After this preparation, I proceeded with the operation in the presence and with the assistance of Drs. Williams, Mitchell, and Smith, of Hampden,

and Prof. Tiffany, of Baltimore. To the last named I feel myself peculiarly indebted, not only for the honor of his presence, but also for his able counsel and assistance during the entire case.

The operation determined upon was that of Sänger. The only circumstances worthy of special note were the behavior of the uterine tumor and the fact that the incision into the uterus was directly on the placenta. The uterus, by its own weight, protruded through the abdominal incision, and lay on a disinfected towel between the patient's thighs. The membranes were still intact; and instead of following the advice of Sänger and others to rupture them at this stage of the operation *per vaginam*, I followed that of Charpentier, and left them intact to the last moment. I was led to do this not on account of any advantage to be derived from such a course in an ordinary case, but from the fact that I would have had to turn my patient on her side in order to reach the membranes *per vaginam*.

It was difficult to raise the uterus enough to incise conveniently the anterior wall; but believing in the advantage of this position for the incision after the completion of the operation, I determined to make it nowhere else. I was unable to discern the position of the placenta, and the incision was immediately over it. I think the unruptured state of the membranes at this time was an exceedingly fortuitous circumstance; for the cavity of the uterus being full, when the organ was incised, instead of contracting on the placenta, as the lips of the wound retracted, the placental attachments were broken up to a large extent. The placenta was quickly separated from the left side of the incision, the membranes ruptured, and the child seized by the feet.

The child was extracted in an asphyxiated condition, the heart, however, was still beating. While Dr. Williams held the rubber cord controlling hemorrhage from the uterus, and I was emptying that organ of the secundines, and by massage bringing about firm contraction, Drs. Tiffany and Smith succeeded in resuscitating the child.

The uterine wound was closed with two rows of stitches, the peritoneal layer with the continuous suture, and the muscularis with interrupted sutures—fourteen in number. The material used for suturing was carbolized silk. The uterus, firmly contracted and free from any leakage, was returned to the abdominal cavity,and the abdominal incision closed.

I cannot state the exact time of operation, but two hours and a quarter were consumed between the placing of the patient on the table, and her return to her bed, with the wounds fully dressed, and her body cleansed. About twenty minutes of this time were taken up prior to delivery, the administration of the anæsthetic consuming part of this. Chloroform was used as the anæsthetic on account of the cough, ether, from its well-known irritant effects, being deemed inadvisable.

The patient was placed in bed, surrounded with bottles of hot water, and a few minims of Squibb's fluid extract of ergot, along with some whiskey, were administered hypodermatically. After complete recovery from the anæsthetic, small doses of tinct. opii deod. and fluid extract of ergot were ordered. Reaction was fair, and the patient was allowed milk in moderate amount.

Twelve hours after the operation, patient was conscious, cheerful, comparatively free from pain; pulse 104 and feeble, temperature normal, lochial discharge normal in amount and appearance. There was one really bad symptom at this time, viz., the secretion of urine was very scanty, the catheter drawing but two ounces.

During the next twelve hours she excreted about the same amount, and despite stimulation the heart's action became more feeble, temperature $99\frac{1}{5}°$ F.

From this time on the patient steadily declined, the symptoms of uræmia predominating. Death occurred on the 16th at 2.30 P. M., sixty-two hours after the operation. There was no vomiting, no hiccough, no abdominal distention, no febrile movement, her temperature never having risen above $99\frac{1}{5}°$ F. Increasing œdema, increasing feebleness of pulse, increasing coma, were all that I could see. It is needless to report the treatment of this condition; purgation with stimulation and fluid nourishment were given a fair trial, but to no avail.

Was this operation a success or a failure? For my own part, although under the circumstances my opinion may be somewhat biassed, I would class it among the successful, rather than the unsuccessful, precedures of obstetrics. My opinion before the operation, was, that it afforded the only means of emptying the uterus, ante-mortem; and I think, had any one else entertained a contrary opinion, he would have changed his mind had he seen the condition of affairs when the abdomen was opened. This cavity, of course, was not kept open long enough to note the position of the abdominal organs, but it was noticed that the ligature around the lower portion of the uterine cone was, while *in situ*, *in contact with the liver*. I had never expected to save the mother, but operated early in order to give her the advantage of any slender hope of recovery which might remain. The child was delivered alive, and still lives—one human life was saved by means of the operation. The history of the case, following the operation, would lead me to hope for better things in a subject reasonably healthy, although seriously deformed.

Here I would like to add my humble opinion as to the place the Cæsarean operation, or one of its substitutes, should hold in the practice of midwifery. It is beyond the province of an article like this to enter into any extended discussion of this important question, and to be brief, I will merely formulate my ideas.

I believe the verdict of the near future will be, that when there is such disparity in size between the maternal pelvis and fœtal head, that the latter cannot engage in the upper strait, the Cæsarean operation is indicated; and that whenever the true conjugate is less than two and a half inches, in ordinary hands,

Cæsarean section is safer than craniotomy or cephalotripsy. Barnes and Jaggard may affirm that in the latter operations the maternal danger is practically *nil*, but the writings of other authorities just as reliable as they, fail to confirm such a statement. Verrier affirms that even Pajot has not succeeded in saving life when the conjugate was under two inches, and Charpentier speaks of thirty-seven maternal deaths in 119 cases (the minimum conjugate being 2.7 inches), as "fairly satisfactory results," from the use of the cephalotribe.

I can never feel that operative interference, which takes into account the interests of the child as well as those of the mother, is to be lightly considered from a moral standpoint, and for one, I will never *willingly* apply a destructive instrument, of any sort, to the head of a *living* child, free above the pelvic brim, and it seems to me that no words could express the consternation and chagrin of one, who was compelled to resort to the Cæsarean operation, after failure of one or other of the destructive operations.

As to the time of operation, common sense, as well as sound surgical judgment, and clinical experience, teach that if the operation is to be performed at all, it should be done before the mother has been exhausted by a protracted labor.

THE TREATMENT OF THORACIC ANEURISM BY IODIDE OF POTASSIUM.

By O. T. SCHULTZ, M.D.,
of Vernon, Ind.

In connection with the very valuable paper on the "Treatment of Thoracic Aneurism by Iodide of Potassium," by Prof. Macdonald, in The Medical News of January 7, the following report of a case of aneurism of the root of the aorta may be of interest, in which the treatment by iodide of potassium procured relief of all the distressing subjective symptoms, and a great improvement in the objective signs for a number of months, and when the treatment was stopped through ignorance and carelessness of the patient, and hard work was continuously engaged in, a new pointing of the aneurism externally occurred, and finally rupture into the right lung and death, while the post-mortem showed what immense amount of repair had being going on, and in what it consisted.

On April 28, 1887, a negro man, probably fifty years of age, presented me a card from Dr. Ramsey, of this city, which informed me that this was an interesting case, and would well repay the trouble of an examination. The patient, a strongly built man, was much emaciated, walked with a tottering, halting step which scarcely left the ground, and seemed much worn out by the short walk from Dr. Ramsey's office, his face expressed great and long continued suffering. He stated that about six years ago he had been for a long time troubled with pain in his joints and limbs. The joints had swelled, first one and then the other, and he had also had some fever at the time. Since then he had dull, sore pain in his right chest, and especially under the sternum, severe enough at times to compel him to take to bed. He had also been having more or less cough, and at times dyspnœic seizures, especially at night. About four months ago a tumor first appeared upon his outer chest wall. For some time past the symptoms had been so troublesome that he had to give up all work and seek medical advice. He further stated that he was under Dr. Ramsey's care, and that he was fast improving, his cough almost gone, his pain much less, no more dyspnœic attacks, his strength was increasing, and that he ate and slept well.

The pulse at the wrists was too indistinct to count. The heart's action was regular, equal, weak, 96–100. The apex beat was in the fifth space, a little internal to the nipple line; the impulse was weak but distinct. The thoracic wall presented no discoloration or enlarged veins. Over the middle of the sternum in the region of the third and fourth cartilages and spaces, there was a tumor the size of a small orange, with a rounded base and a sharply projecting apex. Toward the right of this base the thoracic wall was markedly bulged out. Well-marked pulsation could be seen in the bulging to the right of the sternum, and could be felt, but not seen, in the tumor over the sternum. The sternal tumor was round, about two inches in diameter at base; the bony walls arched up and left an open central spot one inch in diameter with well-marked bony margins, through which projected the pointed apex, which was very soft, and its coverings seemed greatly attenuated. The heart sounds over the apex, over the pulmonary orifice, and over the tricuspid valve below the sternal tumor, were weak but distinct. The heart's action was equal, regular, somewhat accelerated; the rhythm was normal. Over the aortic orifice the sounds were loud, four to five times as loud as over the pulmonary artery; a powerful impulse was present, and a distinct systolic but no diastolic murmur; the murmur was with the first sound, and almost replacing this; the second sound was loud, clear, and distinct; the intervals also were free from any sound or murmur. Pulsation over tumor was synchronous with that of the heart, and stronger to the right of than under the sternum. A systolic murmur was present over the tumor, but whether this was propagated from the aortic orifice, or whether it originated in the tumor, cannot be made out. There was absolute dulness for a hand's breadth to the right of the sternum, over the site of the bulging. The heart's limits seemed normal, except to the right, where the cardiac merged into the tumor dulness.

I diagnosticated thoracic aneurism, and judged the seat of the same to be either the root of the aorta, or the right auricle of the heart. I ventured to recommend to Dr. Ramsey that the patient be put and kept on large doses of potassium iodide, and gave it as my opinion that the patient was probably syphilitic. Dr. Ramsey agreed with me in this opinion, and told me that his patient was now taking five grains of the iodide four times a day, and that

he thought the very manifest improvement must be attributed to this agent.

Sept. 4. Dr. Ramsey invited me to see this case with him. He informed me that the negro had taken the potassium iodide for several months, that he had improved during this time, in every respect, that the sternal tumor had disappeared and the defect in the bone had filled up. In fact, he had considered himself well, had ceased reporting himself, had stopped the medicine, and had been engaged all summer in heavy manual labor, that even yesterday he had seen him raising dirt from out of a deep ditch. Early this morning while still in bed a violent hæmatemesis had taken place, by which he lost three pints of blood. This hemorrhage had ceased spontaneously. We saw the patient at 5 P.M., and found him in a partial stupor, the pupils were normal, the pulse was hard and synchronous at both wrists. Pulsation was much stronger in the right supraclavicular space than in the left. He had no pain, only slight cough and felt comfortable. The sternal tumor had disappeared. The lateral prominence had spread upward and to the right, its highest point being in the upper part of the right thoracic wall, where the second rib had been absorbed. A violent hemorrhage recurred shortly after our visit, in which the patient died.

Post-mortem.—Present, Drs. Powell, Pearse, Ramsey, and Schultz, all of Mt. Vernon. Cadaveric rigidity well marked, body was well nourished, good panniculus adiposus. The contours of left thorax were normal. On the right side the thoracic wall was considerably bulged out, the prominence beginning two inches from the right margin of the sternum and extending four inches transversely, and beginning two and one-half inches below the clavicle, and extending six and one-half inches directly downward. The bulging was considerable, at least one inch in height, and attained its maximum at its upper outer part, external to the nipple line, where it made a sharp boss two inches in diameter and two inches high, and where it had eaten through the rib. Great difficulty was experienced in removing the sternum and cartilages, owing to the very firm and very extensive adhesions on their outer surface. The former defect in the sternum was marked on its anterior surface by a slight depression of normal color with the balance of this bone, and on its posterior surface by a rough, dark-red spot the size of a silver half-dollar. We found that with the sternum and cartilages we had also removed a large part of the anterior wall of the tumor. This tumor occupied the entire front of the upper half of the right thorax and passed over to the left to become continuous with the base of the heart. It was firmly adherent in front to the wall of the thorax, free at its lower and lower posterior part, and so firmly attached at its upper and upper posterior part with the pleura and lung, that it had to be cut out from its neighboring organ, and removed with portions of the lung and ribs attached. It had broken into the right lung at its upper part and the lung tissue was filled with clotted blood. The left lung was not adherent to the tumor. The apex and body of the heart were easily stripped of their covering, but at its base the tumor formed one continuous mass with the heart, and here the pericardium seemed to enter into the formation of the wall of the tumor. The lower half of the tumor was filled with a mass of fibrin of a light-red color, disposed in layers of unequal thickness. This mass was nearly two inches in thickness, and could readily be peeled off from the tumor wall, and then presented at its lower surface the outline of the tumor; its upper concave surface with the upper walls of the tumor had formed the present cavity of the latter which held about one pint and was filled with loose recent clot. The lower walls of the tumor were very thick, dense, and non-adherent, the upper walls were thin, broke down easily and were firmly adherent to the surrounding organs.

The heart was normal in size, form, and consistency, its chambers were of normal size and shape. The valves were normal, except the aortic semilunar, which were slightly thickened, very few and small calcareous granules were present upon these valves and at this orifice, these valves seemed slightly incompetent. Just above the valves the right side of the aortic wall presented a large hole which opened into the aneurismal sac. The root of the aorta and its remaining sinuses seemed to be somewhat dilated, but above the sinuses the calibre of the vessel was not increased. The opening occupied the place of the right posterior sinus of Valsalva, being removed not much more than one-quarter of an inch from the orifice of the coronary artery. It was in the shape of an irregular square and measured three quarters of an inch in breadth and three-eighths of an inch in height. Its boundaries were: the lower, the base of the heart, an almost straight line, the two lateral, the walls of the aorta, also straight lines, the upper, also the aortic walls, irregularly convex. The floor of the opening was smooth, presenting a shining, polished appearance, the walls of the aorta as they constituted the lateral and upper margin of the opening were smooth, well rounded, shining, and showed no signs of ulceration. The upper wall of the aneurismal sac was attached to the aorta, more than an inch above the opening in this vessel, and hence the aortic wall here hung as a screen between the cavities of the aneurism and of the aorta. This portion of the wall of the aorta was also free from disease as far as could be judged by sight and touch. The other vessels of the heart and their orifices were normal.

From a study of this very instructive case we draw the following conclusions: The treatment by potassium iodide had very rapidly relieved the patient of great suffering, and had restored him to a relatively healthy condition; it had stopped the onward progress of the disease; it had prevented rupture through the sternum which at one time was imminent; by the amount of reparative work done in the older part of the tumor, this had been forced into a new direction, when it again began to grow; by a steady continuance of the treatment, by careful diet and rigid abstinence from work and exertion of any kind life might have been preserved a much longer time and the inevitable termination postponed much longer.

ICHTHYOL IN SURGERY.[1]

BY EDWARD MARTIN, M.D.,
OF PHILADELPHIA.

ICHTHYOL was first described by Schrötter, and used in the treatment of skin diseases by Unna. It is obtained as a clear yellow-brown oil, by distilling bituminous matter found in Tyrol, and containing the fossilized remains of fishes and marine animals. By the action of sulphuric acid on this distillate, and subsequent neutralization with soda or ammonia, either the sodium or ammonium sulphichthyolate is produced. The latter compound is preferred by Unna.

The ammonium sulphichthyolate is a reddish-brown, clear, syrup-like liquid, of burning taste and odor, soluble in water, making a clear red-brown solution; also soluble in equal parts of alcohol and ether.

The ichthyol preparations are characterized chemically by their richness in sulphur (ten per cent.), so intimately united that it can only be extracted by complete decomposition (Lartigeau); they easily take up oxygen, acting as powerful reducing agents (Baumann).

Clinically, the ichthyolates are described by Unna as being powerful antiphlogistics, causing anæmia and rapid subsidence of swelling in all tissues. This antiphlogistic effect is ascribed to the drug's action on the endothelium of the bloodvessels, depriving it of oxygen by virtue of its reducing properties, and contracting the lumen of the vessels. This explanation is not, perhaps, entirely satisfactory, but physiological studies have not yet given us a better one. The cornifying effect of the drug on the epithelium of the rete is undoubted.

Surgically, what are the indications for the drug? Lartigeau states that it is indicated in all subcutaneous and inflammatory tumefactions, œdemas, vascular dilatations, incipient furuncles, and local manifestations of rheumatism. Elliot praises it highly in burns of the first and second degree (five per cent. solutions in water), as producing rapid subsidence of pain and inflammatory symptoms. He finds its application to obstinate varicose ulcers associated with eczema rubrum (sodium compounds, three to five per cent.) at times productive of marvellous results. In his hands it is also useful in cicatrices, and in a few cases of rheumatism and neuralgia has given immediate and marked relief from pain. Schweninger states that in rheumatism, lumbago, ischias, tic, gout, and migraine, local applications of ichthyol act more powerfully in allaying pain than any known medication.

Lorenz is astonished at the fabulous efficacy of the drug. In acute and chronic joint rheumatism, acute muscular rheumatism, mastitis, panaritis, and contusions, a few rubbings with pure or fifty per cent. ichthyol compounds are peculiarly successful in allaying pain and hastening healing. In chronic and acute joint rheumatism relief often follows a single rubbing, while this is the rule in acute muscular rheumatism. The pain of gout disappears, the shining red skin becoming quickly wrinkled. A beginning mastitis or panaritis is always aborted, or if fully developed the pain is much relieved. Its prompt use prevents the discoloration following contusions. It immediately allays the pain of a burn, and prevents blistering. Finally, a ten per cent. solution hastens the cicatrization of badly healing ulcers.

Loring dilutes with water when the pure ichthyol compound cannot be borne and prevents irritation of the skin by careful washing and drying before each application.

Von Nussbaum states that a single application of ichthyol one part, water four parts, lanolin five parts, has allayed the itching of eczematous ulcers which had resisted all known applications for weeks and months, and promptly brought about rapid cicatrization on being continued a few days. Arthritic pains, which for weeks have made day and night miserable, are relieved at times in one-half minute after the application of a strong ichthyol ointment. In erysipelas it produces results obtainable by no other means, namely, the immediate arrest of the disease.

Von Nussbaum's treatment was first the thorough disinfection and drainage of the wound, then, if the disease continued to extend, over its whole surface a thick layer of ichthyolate and vaseline, equal parts, was spread and covered by a layer of ten per cent. salicylated cotton. The erysipelas advanced not a line further and in a single day the swelling disappeared, and the red, shining, puffy surface became yellow, brown, and wrinkled. This remarkable effect von Nussbaum ascribes not to the influence of the drug on Fehleisen's cocci, but rather to a change produced in the tissues by virtue of which they cease to favor the growth of the microörganisms.

Stelwagon has had excellent results in the abortion of furuncles by ichthyol preparations. D. Hayes Agnew considers the ichthyol preparations more powerful than any known therapeutical agent in bringing about reduction of inflammatory enlargements, and has had particularly good results in recently enlarged lymphatics. He uses sulphichthyolate of ammonia and iodide of lead, equal parts, applied generously and covered in by oiled silk.

The writer has used ichthyol in:

(1) Six cases of cervical adenitis, with absolutely no relief; cure being subsequently brought about by iodine or the knife.

(2) Fifteen cases of marked inflammatory induration of the subcutaneous tissues, with invariably a

[1] Read before the Philadelphia County Medical Society, January 25, 1888.

speedy, and in some cases, almost magical reduction, and this after other means had been tried unsuccessfully.

(3) In two cases of furuncles without good effect.

(4) In one case of cellulitis without marked effect till the knife was used (in this case staphylococci were found, but no chains).

(5) In four cases where pain was the most marked feature of inflammation, with complete relief in three, and no effect in the fourth.

(6) In one case of erysipelas of the scalp, with immediate cure.

The latter is so striking, that it is reported in full.

B. C., bartender, æt. thirty-six; Irishman. Struck on the head by a bottle whilst intoxicated, December 20, 1887. Two slight wounds of the scalp, to which no dressing was applied. 22d. Chill, fever, nausea, great pain in the head, and swelling. Went to a clinic; wounds were opened, disinfected, and catgut drainage provided; symptoms progressive. He was seen by the writer on the second day of his fever, the fourth from the infliction of the wound. No sleep for two nights. Pulse 106; temperature 103°. Violent headache; whole scalp puffy, œdematous, and very tender; a few drops of thin pus squeezed from wounds. Cover-glass preparations of blood from puncture by tenotome showed Fehleisen's chains. A saline purge and iron were ordered internally. On the scalp was placed a thick layer of ammonium ichthyolate and vaseline, equal parts. The pain was relieved almost immediately; the patient slept comfortably; his temperature the following morning was 98°, and he was and remained well.

This is not different from the results obtained by Nussbaum.

With the exception of the case of erysipelas, the writer used a ten per cent. ointment of ammonium ichthyolate in lanolin, fearing lest, in the case of stronger applications, his effects might be ascribed to counter-irritation. It is possible that stronger preparations would have proven efficacious in the treatment of adenitis in which the weak ointment signally failed.

The extravagant praises bestowed by some authors on ichthyol savor more of proprietary advertisements than scientific contributions, and the variety of affections for which it is recommended might well make one doubtful as to its complete efficacy in any single instance.

An analysis of the cases in which it has proven serviceable will show, however, that they can be relegated to one of two classes:

1. Affections characterized by inflammatory enlargement.

2. Affections characterized by pain of peripheral origin, probably depending on inflammation or congestion.

For either of these conditions, theoretically, a powerful antiphlogistic would be indicated, so that the clinical indications for the use of the drug correspond to its alleged therapeutic effect.

When the surface is irritated, weak solutions (three to five per cent.) should be used; but when the skin is intact and the subcutaneous tissues are to be affected, pure or one-half strength ointments give the best results. In using strong preparations the skin should be washed with soap and warm water, and thoroughly dried before each application. Ichthyolates can be combined with any of the ointments, or can be dissolved in water.

The writer's success with the drug, even where it was not used in the most efficient manner, has convinced him that the praise bestowed on it by the Germans is well merited. Where suppuration has actually taken place the weak ointment is not of service, but in the allaying of inflammatory pain and the resolution of subcutaneous induration (excepting adenitis) the results are most satisfactory.

MEDICAL PROGRESS.

Laryngeal Perichondritis.—At a recent meeting of the "Wiener Medizinisches Doctorencollegium," Professor Schnitzler showed a very interesting case of laryngeal perichondritis of a doubtful character, which was completely cured by the use of iodide of potassium. The case was especially interesting from a diagnostic, as well as therapeutic, point. The patient, an apothecary, thirty years old, fell ill about a year ago with a cough, hoarseness, pains in the throat, and disturbances of swallowing. He was for a long time treated as an out-door patient at a certain clinic, but the diagnosis made there could not be found out. The patient stated that his larynx had first been treated with glycerine of iodine, and later on with the nitrate of silver. When admitted into the Polyclinic of Vienna considerable swelling of the whole laryngeal mucous membrane was found on examination; the epiglottis was particularly much reddened and thickened, and on both sides of it there were ulcerations, which extended over the "plicæ aryepiglotticæ." The seat and the appearance of the ulcerations immediately made the presence of a syphilitic affection probable, and this so much the more as the mucous membrane between the arytenoid cartilages was rather intact. The patient stated that he had, indeed, about twelve years ago, suffered from a catarrh of the urethra, with consecutive swellings of the inguinal glands, but that he had never suffered from syphilis, in the proper sense of the word. A sure diagnosis as to the presence of laryngeal syphilis was so much the more difficult as owing to an affection of the lungs, which could be proved by their examination, tuberculosis of the larynx was at any case possible, though tubercle-bacilli could not be detected in spite of repeated examinations.

Taking into account these conditions, Prof. Schnitzler first ordered the use of iodoform by insufflations into the larynx, and as these were not attended with any success, he ordered a systematic inunction cure for several weeks. All these procedures, however, failed, and the laryngeal

process, on the contrary, made further progress. In August and September the swelling of the whole laryngeal mucous membrane increased to such a degree that on account of the immobility of the arytenoid cartilages and the thickening of the vocal cords, the "rima glottidis" appeared to be quite closed, and the space for the passage of the air was reduced to a minimum. The disturbances of respiration had attained such a degree that tracheotomy was seriously taken into consideration. Though, owing to this course of the disease, the diagnosis of syphilis became more doubtful, Prof. Schnitzler, nevertheless, persisted in his first opinion, and now ordered the use of iodide of potassium in large doses, such as from 45 to 60 grains a day; The effect of this medication was quite surprising. The cough, hoarseness, and disturbances of swallowing soon decreased, the respiration became easier and freer, and the whole condition of the patient greatly ameliorated. The ulcerations completely cleansed and healed, though rather large scabs still remained. At present all was cicatrized, and there was no longer any trace of the ulceration. Only the middle part and the margins of the epiglottis, as well as the epiglottic plicæ, were transformed into a narrow scar; the arytenoid cartilages were almost of a normal appearance, and moved on phonation as well as on respiration quite freely. Prof. Schnitzler emphasized the special difficulties of the diagnosis in this case and wished emphatically to direct the attention to the success of the course of treatment.—*Medical Press and Circular*, Jan. 11, 1888.

Powders for the Treatment of Coryza.—VIGIER, in the *Journ. de Méd.* of January 8, 1888, gives the following formulæ:

℞.—Morph. hydrochlor. . . gr. ¾.
Pulv. gum. acac. . . . ℥i.
Bismuth. subnitrat. . . . ℥i½.
Pulv. althaeae . . . ℥i½.—M.
Sig.—By insufflation in the nares.

℞.—Amyl. pulv.
Acid. boric.
Tinct. benzoin. . . āā ℥ii½.

Mix, triturate, sift, and dry. If desired, 1½ grains of morphia hydrochlorate may be added.

What Antiseptics may be Used About the Eyes.—DR. WEEKS, of New York, in an article in the *Archives of Ophthalmology* for December, 1887, reports the results of his studies on this question, as follows:

The results of these experiments, confirming in greater part the results obtained by others, indicate as efficient antiseptic remedies, which can be used on the tissues without causing undue irritation, the following substances:

Bichloride of mercury, 1 : 1000 to 1 : 2000 on cut surfaces, on suppurating surfaces, and on the integument; 1 : 4000 to 1 : 8000 on mucous membranes.

Nitrate of silver, 1 : 100 to 1 : 500 on mucous membranes and on suppurating surfaces.

Chlorine water on mucous membranes and on suppurating surfaces.

Hydrogen dioxide as chlorine water.

Carbolic acid, 1 : 40 on cut surfaces and suppurating surfaces and on the integument.

Permanganate of potash, 1 : 100 to 1 : 200 on cut surfaces and on suppurating surfaces.

Alcohol, 66 per cent. on the integument and on suppurating surfaces, as in otorrhœa.

The *oil of cade* may be used to advantage in eczema, on account of its antiseptic and germicidal properties. *Calomel* is by far the most efficient antiseptic remedy in the form of powder that we have. *Iodoform*, which is highly valued by some oculists for use in infiltrated ulcers of the cornea, in gonorrhœal ophthalmia, and for the dressing of wounds, may be of service if it can be kept in contact with the parts for a number of hours. It is not irritating to mucous membranes or to cut surfaces, but is very slow in its antiseptic action.

Antiseptic dressings, so-called, are usually only aseptic. In order that bacteria may develop, it is necessary that they be on a surface containing 50 to 70 per cent. of water. We can thus readily see that bandage material must be free from all germs but those that are deposited on it from the air or from objects that it comes in contact with. It is antiseptic only when impregnated with an antiseptic substance and moistened. So long as a wound can be kept dry, healing will progress without the formation of pus, whether it is bandaged or not, simply because germs cannot develop if moisture is not present.

Mechanical, combined with *thermal*, sterilization in the use of hot water, is recommended as the best method of sterilizing instruments. As, however, the procuring of hot water is attended with some degree of trouble, and as a solution which can always be kept ready is more convenient, the combination of the mechanical with the chemical will probably be most used. The water used should be previously boiled and the antiseptic employed be either bichloride of mercury (1 to 2000), carbolic acid (1 to 20 or 1 to 40), or salicylic acid (1 to 1000). These act promptly and are efficient.

To cleanse the site of the operation soap and water should be used to remove oily substances and rough dirt, followed by a solution of bichloride 1 : 2000 to 1 : 5000 for germicidal effect. The surgeon's hands may be cleansed with a solution of 1 : 2000.

Hypnone, or acetaphenon, may be given in doses of ¾ of a minim to 3 minims, with caution, best administered in oil or ether, in capsules:

℞.—Hypnon. . . . . gtt. 4.
Ol. amygdal. dulc. . . . ♏ 8.
In 10 capsules.
Sig.—One or two capsules before retiring.

According to our present knowledge the value of hypnone is not clear; in some cases it has produced headache, and a very unpleasant taste.—*Deutsche med. Wochenschrift*, January 5, 1888.

The Treatment of Carotid Hemorrhage.—TREVES, of London, describes the following procedure, in the *Lancet* of January 21, 1888, which he employed successfully in four cases, one of which he describes as follows:

In the neck, pressure upon the carotid artery cannot be applied with success, or maintained for a serviceable length of time. The vessel can, however, be very readily occluded for a while and the carotid circulation arrested without the artery being permanently closed. This is effected by exposing the artery in the usual way

and passing around it a thick piece of soft catgut. This is tied in a very loose loop. By pulling upon the loop the circulation through the vessel is at once arrested, but is, however, at once restored when the tension upon the loop is relaxed. Without discussing the possible value of this procedure, the following case may be briefly detailed.

A man, aged twenty-five, was brought to the London Hospital in 1880, bleeding profusely from a deep wound in the neck, about the level of the great cornu of the hyoid bone. While attempting to open a soda-water bottle the bottle burst, and a fragment of glass was driven into the neck. The cut made was less than one inch in length. The glass had been removed. The bleeding had been very profuse, and was arterial. The patient was blanched and almost insensible. The radial pulse could scarcely be felt. The bleeding was for the time checked by pressing a tampon against the wound. It was obviously useless to attempt to find the bleeding point while blood was welling up from so deep a wound. I, therefore, at once exposed the common carotid artery through a lower incision and placed a catgut loop around it. Traction upon this arrested all bleeding. The patient was placed in bed and surrounded by warm bottles. His condition was so grave that I did not feel disposed to search for the bleeding point. Traction upon the loop was maintained for half an hour. On relaxing the catgut no bleeding took place, and it never again recurred. The loop was left *in situ* for four days, when it was removed. The man, who was in vigorous health at the time of the accident, made a rapid and uninterrupted recovery. I supposed the bleeding to have come from the superior thyroid artery.

Alcohol for Children.—Jacobi, in the *Archives of Pediatrics* for January, 1888, writes that alcohol has conquered its place among the medicinal foods in the diseases of infancy and childhood. Very little, if any, is required in catarrhal, or the first stages of inflammatory, diseases. It is contraindicated in meningitis, acute cardiac ailments, gastro-enteritis, peritonitis, and acute dysentery. It finds its application in depressed strength and vitality; thus, in the rules for the management of infants during the hottest days of summer, which the Health Department of the City of New York has published annually these fifteen years, he recommended the administration of a teaspoonful of whiskey daily. It is also required in chronic diseases and slow convalescence.

Its action is stimulant, nutritive, antipyretic, and antiseptic. It is decomposed into carbonic acid and water, and thus saves the waste of material parts of the body. When given in sufficient quantities, it reduces the temperature; the amount required for that purpose is, according to Binz, forty grammes, corresponding with about three ounces of brandy or whiskey. Its most beneficial action is exhibited in sepsis of all forms, mainly also in the septic variety of diphtheria. It is almost impossible to give too much. The doses must be watched so as to be sufficiently large. Whoever is not afraid of giving six ounces of whiskey daily to a child when one or two fail, or ten or twelve when six fail, will soon convince himself of its power for good. It must never be given in concentration; the gastric mucous membrane tolerates no pure brandy or whiskey for any length of time; they must be diluted with either water or milk properly prepared. Wines, brandies, and whiskeys are not equivalent. The latter is obtained pure with greater facility, and at less expense, and besides has, for many, a less disagreeable taste than either of the others, which are often adulterated. The ether contained in wines militates against any antifebrile effect which may be expected from it; the fusel oil with which brandies are too frequently adulterated, acts rather as a paralyzing than as a stimulating agent.

Benzol in Whooping-cough.—Dr. J. Lowe highly recommends benzol as a remedy for whooping-cough. To deprive the benzol somewhat of its hot, burning taste, and to prevent it from causing nausea, he advises it to be administered in a viscid mixture, and in small doses, usually in quantity of three or four minims. Yet even smaller doses are effective, and for a child four or five years of age two minims every two hours will be sufficient. The following mixture is recommended by him:

R.—Benzol. puriss.	♏32.
Glycerini	fl. ℥ i½.
Ol. menthæ pip.	♏10.
Syr. mori	fl. ℥ ½.—M.

A teaspoonful every two hours.

[In place of syrup of mulberries, some other pleasant syrupy vehicle, such as syrup of raspberries, may be used.]—*British Medical Journal.*

Oleate of Atropine in Suppositories is recommended by J. F. Brown, of Dover, England, as a substitute for extract of belladonna. Ten grains of atropine dissolved in a half-ounce of oleic acid and diluted with oil to a fluid-ounce and twenty minims, will form a solution of which each minim will represent one grain of the extract.—*Pharmaceutical Journal.*

The Treatment of Ophthalmia Neonatorum.—Mules, of the Manchester Eye Hospital, in a Prize Essay published in the *Medical Chronicle* for January, 1888, describes the following treatment:

The mother or nurse should first wash the eyes in warm water to remove the secretion and free the lids. The surgeon should be seated in a convenient chair, with a folded towel across his knees, and with medical appliances within reach of his hand. These appliances are: (1) A plentiful supply of pieces of clean rag; (2) solutions of argenti. nit., 5 grs. to oz., and 10 grs. to 1 oz.; (3) vessel of clean water; (4) two camel's-hair pencils to apply the solutions and wash the excess of fluid away; (5) a bottle of eserine, 5 grs. to 1 oz., and dropper; (6) lid elevators. He then receives the head between his knees, yet supported by the towel. The nurse tucking the child's legs under her left arm, supports the body on her raised knee, holds the child's hands with one hand, and has the other at liberty to assist the surgeon. The surgeon first proceeds to examine the condition of the cornea by gently raising the upper lid with his finger—if there is any difficulty in this manœuvre he uses an elevator. A bent hair-pin often answers admirably. He next everts the lids, wipes them dry, paints them with the silver solution of the required strength, taking special care to get the *back folds of the conjunctiva*, and washing off the excess of solution with clean water, carefully replaces the lids by drawing them

downward and away from the globe. This process is repeated by the surgeon every morning until the disease is arrested, his object being to produce a slight eschar, which either destroys the microörganisms or prevents their multiplication. The effect lasts about twelve hours. In severe cases the solutions can be reapplied at night. However careful the surgeon may be his efforts are of little avail unless he is ably seconded by the nurse. Her duties are—to prevent the recollection of pus, by constantly opening the lids and wiping the matter away with clean rags; to wash the conjunctivæ with a weak alum or boracic acid solution, 3 grs. to 1 oz.; to anoint the lid margin with cerate to prevent adherence, and to combat the feverish restlessness by fresh air and careful attention to diet.

Menthol in Laryngeal Phthisis.—BEEHAG, of the Royal Infirmary, Edinburgh, reports his use of menthol by insufflation and by applications with a brush or swab as follows:

With the object of securing more prolonged contact with the diseased tissues in phthisis laryngea when there is much secretion present, I have introduced a powder to be insufflated alternately with the injections. The formula is as follows:

R.—Menthol . . . . . ʒss.
Ammon. chlor. . . . . ʒjss.
P. acid. boric. . . . . ʒj.—M.

The same powder, when pulverized very finely, will be found to be very useful in chronic laryngeal catarrh, and the after sensations are not so unpleasant as those which follow upon the insufflation of ordinary powders.

In cases of chronic pharyngitis with hyperæsthesia or paræsthesia I use the well-known Mandl's formula with menthol superadded, the prescription being as follows:

R.—Iodi. . . . . gr. vj.
Potas. iod. . . . . gr. xx.
Aquæ . . . . . ʒiij.
Menthol . . . . . ʒjss.
Glycerini . . . . . ʒvj.—M.

The menthol, which should be powdered very finely, is for the most part here suspended in a fine state of division, and the mixture requires to be shaken occasionally. —*Edinburgh Med. Journal*, January, 1888.

Litholeine.—NOEL, in the *Gazette Médicale de Paris* of January 31, 1888, reports the advantages of this substance, which is a product from the distillation of petroleum. It is an oily liquid, yellow in color, free from fats and resins. Its reaction is neutral, it contains traces of calcareous materials, and is insipid and odorless. Clinically it has proved useful as a substitute for solid and liquid vaseline; it possesses antiseptic and antiparasitic properties, and has been used with the best results in eczema and parasitic skin diseases.

The Treatment of Diarrhœa with Greenish Stools, in Infants.—In THE MEDICAL NEWS of July 9, 1887, page 47, we described a method of treating the diarrhœa of nurslings, characterized by greenish stools, practised by HAYEM, of Paris. He has continued his clinical studies on this subject, and in the *Gazette Hebdomadaire* of January 20, 1888, he reports that he has extended his treatment to adults and finds new evidence of its value. The treatment consisted in the administration of lactic acid, in convenient menstrua, as a germicide for the bacillus present in the intestines of these patients.

SEVESTRE has also arrived at similar conclusions by clinical research, and reports that he has obtained good results by using the remedy in larger doses than Hayem employed, he had given a teaspoonful of lactic acid, 1 to 50, with simple syrup every ten minutes in grave cases. In "bilious diarrhœas" he had obtained good results from large doses of sodium bicarbonate.

Saccharin in Various Combinations.—CHUCHE, in the *Revue Gen. de Clin. et de Thér.*, January 5, 1888, gives the following formulæ for various combinations of saccharin:

R.—Quiniæ sulphat. . . . . gr. 8.
Acid. sulphur. . . . . q. s.
Essen. menth. piper. . . . gtt. 5.
Solut. saccharin. . . . . gtt. 10.
Aquæ destillat. . . . . gtt. 100.

R.—Rhei pulv. . . . . ʒ 2½.
Saccharin. . . . . ʒ 2½.
Syrup. fœniculi . . . . gtt. 4.

R.—Chloral. hydrat. . . . . ♏ 75.
Solut. sacchar. . . . . ♏ 75.
Aquæ destill. . . . . ʒ 25.

R.—Sodii bicarb.
Acid. tartaric. . . . . āā ʒ 2¼.
Saccharin. . . . . gr. 30.

[The superiority of saccharin to sugar, as a sweetening agent, makes it most convenient in combination; the solution mentioned is undoubtedly a saturated one.

These formulæ are intended merely to indicate some of the combinations most generally used, without specifying dosage.]

Ichthyol, Internally.—VON NUSSBAUM, of Munich, has observed that ichthyol is of value, administered internally, in conditions of gout, rheumatism, and capillary engorgement from varying causes.

He prescribed it in pills, each containing one and a half grains, and gives it in increasing doses, until the patient takes from seven and a half to ten grains morning and evening. When good results are obtained the remedy may be discontinued, but on an exacerbation of rheumatic trouble the full dose last given should be employed at once.

With the exception of a few cases, who could not take the remedy in small doses, no unpleasant effects were seen.

Von Nussbaum, by way of experiment, took seventy-five grains of ichthyol in twenty-four hours without inconvenience.

In a few patients he found that it excited a tendency to eczema.—*Therapeutische Monatshefte*, January, 1888.

Rectal Feeding.—From a study of the subject of rectal alimentation, DR. WEAVER (*Transactions of the Luzerne County Medical Society*) has formulated the following conclusions:

1. By the use of enemata life can be sustained indefinitely with little, if any, loss of weight to the body.

2. In a large proportion of cases in which rectal aliment is used, true digestion of albuminous, saccharine, and fatty food takes place, by virtue of inhaustion, or a reversal of the normal peristalsis of the alimentary tract.

3. While this is the case, there are doubtless instances in which retrostalsis does not occur, and for that reason the food used should first be artificially digested before being injected into the rectum.

4. While milk, eggs, and brandy are the best aliment for rectal nutrition, no one article should be used for too long a time, but frequent changes should be made, observing the greatest care to prevent irritation of the rectum, or intolerance of that organ for the nutriment required.

5. The enemata should, if possible, be administered by the physician himself. Where difficulty in retaining the aliment is encountered, the colonic method is preferable, the food being propelled through a rectal bougie. The food should be of the temperature of the body.

6. The rectum having once become intolerant of enemata, *absolute rest* must be given to that viscus for a few days, and reliance be placed on nutritious inunctions of the surface of the body.

7. For rectal alimentation there exists a wider range of usefulness than has heretofore been assigned to it. It is not only appropriate in the severer forms of chronic disease of the stomach and œsophagus, but is indicated and should be utilized in the management of all *acute* diseases when, from any cause, the stomach becomes intractable and rebellious.

8. In diseases of the stomach, even where a portion of the food ingested is retained by that organ, only to undergo fermentation, inducing thereby pain and distress, it is more logical to resort to rectal alimentation, not as an *adjunct* to, but a *substitute* for, stomachal ingestion.

9. Certain organic lesions as well as functional disturbances of the stomach are curable by means of rest to that organ, and by no other means. In rectal alimentation we have a safe and sure means of nutrition, pending the necessary period of rest to that organ. — *Dietetic Gazette*, January, 1888.

The Influence of Tissue Changes in Producing Uterine Flexions.—GRAILY HEWITT, in the *Medical Press and Circular* of January 11, 1888, summarizes his views on this point as follows:

1. Undue softness of the uterus associated with defective nutrition either in nulliparous or in parous cases usually precedes flexion. 2. Flexion then occurs. 3. The flexed and soft uterus readily becomes congested. 4. The congested flexed uterus generally becomes hypertrophied. 5. The flexion now permanent is an obstacle to removal of congestion. 6. Compression of uterine tissue caused by flexion is an important element in chronic metritis. 7. Endometritis is, as a rule, a secondary effect of chronic general congestion of the uterus.

For Eczema.—BROCQ, in the *Revue Gén. de Clin. et de Thér.*, January 5, 1888, prescribes the sodium salts as follows:

℞.—Sodii salicylat.
Sodii benzoat. . . . āā gr. 30 to 75.
Sodii bicarbon. . . . . ʒ 2½.
Aquæ destill. . . . . ℥ 12½.

Any compatible tincture or syrup may replace a part of the water.

Dose two to four teaspoonfuls, or a tablespoonful daily.

Arsenic and sodium may be given in

℞.—Sodii arsen. . . . . gr. ⅓.
Sodii benzoat. . . . . gr. 30 to 75.
Sodii bicarb. . . . . ʒ 2½.
Aquæ . . . . . ℥ 12½.

This prescription may also be varied, in its vehicle, as needed.

Dose two to four teaspoonfuls daily.

Meat in Phthisis.—COHEN, in the *Dietetic Gazette* for January, 1888, writes as follows:

The opinion most widely prevailing at the present time assigns the first rank as an aliment in phthisis to flesh, and more especially to beef. The results obtained by certain individuals, who devote themselves to the treatment of disease by an exclusive diet of beef prepared in a certain and most excellent manner, conjoined with lavatory potations of hot water to prepare the digestive canal for the reception and disposition of the aliment, cannot be ignored, whatever we may think of the theories and methods of the practitioners in question. Without confining themselves to beef, scientific physicians are justified in giving it the first rank.

It should be taken at least twice daily, three times if possible. It may be eaten raw, as it comes from the butcher, or it may be chopped finely, seasoned to taste, and made into little cakes, which are eaten raw or slightly browned on the gridiron. It may be taken in the form of rare beefsteak broiled in its own fat, or as very rare roast beef. Other methods of cooking are to be prohibited. The meat is to be as juicy as possible and fibrous portions are to be removed.

Very often one can be satisfied with the use of butcher's meat, raw or cooked as above. Sometimes, however, whether from partial failure of digestive powers or other conditions necessitating reduction in bulk without loss of nutritive material, or suggesting conservation of the energy that would be expended in digestion, it becomes necessary to resort to special methods of preparation. The meat powders prepared by various pharmacists, more especially for forced feeding, here render valuable aid. By cutting boiled beef into fine pieces, drying by means of a water bath, and grinding in a coffee mill with the teeth set closely, an excellent meat powder may be made in the kitchen. (Dujardin-Beaumetz.)

The preparation from which the writer has seen the greatest benefit, and which he is in the habit of most frequently prescribing, is Beef Peptonoids. Whether from improvement in the process of manufacture, rendering it more palatable, or from decrease in the fastidiousness of patients, there has not recently been the same difficulty in getting patients to persevere in the use of it that was experienced in former years.

The methods of administration may be varied almost indefinitely. It may be added to soups and broths, to milk punch, egg-nogg, etc., taken in warm or cold water, or made into a paste with milk or water and spread upon bread. Beginning with a teaspoonful three or four times a day, the amount is to be increased as soon as the preferable method of administration is determined upon, to a tablespoonful or more. It is preferably given among the supplementary articles of diet, between meals.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, FEBRUARY 11, 1888.

ISCHURIA FROM PROSTATIC HYPERTROPHY.

DURING the past year, several interesting contributions have been made to the subject of retention of urine from enlargement of the prostate gland, which throw some light upon the benefit to be derived from excision and incision of the obstructing body. In a paper read at the Clinical Society of London on November 11, and recorded in the *British Medical Journal* of November 19, 1887, MCGILL narrated three cases in which he had resorted to epicystotomy, and removed with scissors and forceps the hypertrophied median portion, with the result of enabling the patients to dispense with the use of the catheter. In these cases, the retention had existed, respectively, for five weeks, seven months, and three years, and was complicated by calculi in one, and by fetid urine in two.

Suprapubic prostatectomy opens up a new field for the operator in a class of cases that have always proved to be a source of great anxiety to the surgeon, and suffering to the patient. One of its advantages is that it does away with the necessity of permanently wearing a tube to drain the bladder; but how far it will prove applicable to all cases of retention from a valve-like projection of the median portion of the prostate will have to be determined by extended experience.

It can scarcely be admitted that, except in comparatively recent instances, ischuria is due solely to the enlarged middle lobe. The longer the retention exists, the more and more surely do the muscles of the bladder become incapacitated for the performance of their function, until, finally, in old-standing cases, the viscus is paralyzed, and the neck of the bladder embedded in the enlarged prostate is rigid. In cases of this kind, the extirpation of the obstructing portion will do no good, as is exemplified by the examples of epicystotomy with removal of the median lobe with the galvanic cautery, related by BENNO SCHMIDT, of Leipzig, at the last Meeting of Naturalists and Physicians at Wiesbaden, and recorded in the *Wiener med. Presse*, No. 51.

In the third edition of his *Lectures on the Surgical Diseases of the Urinary Organs*, lately issued, HARRISON states that he has done prostatotomy over twenty times, but he unfortunately does not give the detailed account of his cases which the profession has a right to expect. His results are summed up as follows: "Not a single instance has yet happened where I have regretted having done the operation, or directly or indirectly connected the death of the patient with the proceeding. In two instances only, so far as I know, did the patients die; one three weeks after the operation, and the other four. Both lived longer and more comfortably than they would otherwise have done, and had nothing to regret in what was undertaken for them. Both patients showed after death a condition of the urinary organs which was beyond repair." In the remaining cases, we are led to infer that the results were satisfactory, and in the three cases in which the histories are given, the patients were well, and had discarded the catheter for respectively six, twelve, and eighteen months.

BOTTINI, at the meeting of the Italian Medical Association at Pavia, of which a note may be found in the *Annales des Mal. Gén.-Urin.* for December, has also recorded favorable results from his operation of internal prostatotomy with the galvanic cautery, a procedure which he has resorted to for upward of ten years.

Incision and excision of the obstructing portion of the prostate have, more especially in view of their safety, been too much neglected by surgeons. We are firmly convinced that they should be subjected to unprejudiced and extended trial, since the meagre accounts we have presented of their results show that they are capable of affording permanent relief, despite the dogmatic assertion of a recent writer in Heath's *Dictionary of Practical Surgery*, that they are "worse than useless."

THE CAUSATION OF TYPHOID FEVER.

Though the bacillus of Eberth, Koch, and Gaffky is recognized by bacteriologists and practical pathologists as the cause of typhoid fever, this relation seems not correctly estimated by hygienists and clinicians. This is especially true in America, for which reason the observations of Vaughan and Novy, published in The Medical News of January 28th, deserve more careful attention than even their great intrinsic value would entitle them.

The researches of the last seven years prove the presence in all cases of typhoid fever, in the intestinal lesions, mesenteric glands, spleen, and liver, of a bacterium which possesses distinct peculiarities of form, size, mode of growth, and reaction to coloring matters, as well as a distinct chemical product or ptomaine. These facts, with the absence of the bacillus in other diseases, and its presence in water and milk suspected of having caused typhoid fever, would alone almost suffice to establish its causal relation. The crucial experiment of producing the same disease in animals by pure cultures of the bacillus failed. This failure, however, was due to the fact that none of the domesticated animals acquire typhoid fever when exposed to the same causes as man in various epidemics. In this respect typhoid fever corresponds to cholera, and just as Koch found that by changing the habit, so to speak, of the animal intestine, it became a suitable nidus for the development of the cholera germ, so Seitz was able to produce a peculiar disease by proceeding in the same way and injecting cultures of typhoid bacilli. These experiments were repeated and modified in various ways, with the result of proving that not only cultures of the bacillus, but even such as were sterilized or freed from germs, produce in animals a distinct disease.

It is, therefore, evident, that the bacillus acts not only locally, as in the production of intestinal lesions, but also that it produces chemical substances belonging to the class of poisonous ptomaines. This goes far in explaining some peculiarities in the clinical course of typhoid fever. The ptomaine isolated by Brieger from cultures of the bacillus, named by him typhotoxine, does not seem able to produce all the symptoms, notably fever, one would expect from such a principle. The product obtained by Vaughan and Novy seems to fulfil the conditions to a greater degree, though as their investigations are as yet not complete it is too early to base any theories on it. It is important to bear in mind that in the lower animals typhoid material produces an intoxication, rather than an infection, but nevertheless an intoxication which is distinctive and caused by a distinct substance. Still, it is by no means indifferent whether cultures or their products be used in the experiments. In the latter case much larger doses are necessary to produce a given effect, a thing easily explained by the fact that the bacilli can live for hours or days in the animal body, and during that time, of course, continue to produce ptomaines.

The already large amount of testimony showing the occurrence of the direct cause of typhoid fever in drinking water is increased by this work of Vaughan and Novy. As this relation was well known even in pre-bacterial days, it is not likely the present lesson will be heeded by sanitarians any more than the former ones. Fortunately, however, there is promise of another means of prevention, namely, by inoculation. Beumer and Peiper, in an extensive series of experiments (*Zeitschrift für Hygiene*, Bd. 2, Heft iii.), found that by using cultures which had been sterilized by heat they could produce in guinea-pigs a condition which presented the same symptoms and anatomical changes, and caused death in the same time as did the live bacilli, uniformity of dose being understood. By a gradual treatment of the animals with such cultures, beginning with the minimal dose and increasing it slowly, it was found that the guinea-pigs acquired perfect immunity toward doses ordinarily lethal. In their first series of such experiments, out of eleven animals only one died, and there is no reason to doubt that with more experience perfect results can be obtained. This certainly seems more promising than any method yet proposed for preventive inoculation.

The next thing to do, as Beumer and Peiper say in conclusion, is to ascertain, in man, the respective roles of bacillus and ptomaine. This having been learned, and the technique of inoculation having been perfected, there would be no reason to hesitate in making cautious experiments on human beings, experiments which, when we regard the ravages of typhoid fever, would be quite as justifiable as those being made on such an enormous scale for a disease so comparatively rare as hydrophobia.

SUCCESSFUL SPINAL SURGERY.

Mr. Victor Horsley has recently applied the principles of treatment which have guided him in cerebral surgery to the treatment of spinal affec-

tions. At a late meeting of the London Medical and Chirurgical Society a private patient of Dr. Gowers and Mr. Victor Horsley very generously allowed the Fellows and visitors of that Society the opportunity of seeing all that had been done for the improvement of his condition. He had spent about three years in severe pain, which was most intense just below and inside the angle of the left scapula, and was accompanied by absolute loss of motion and sensation of the body and limbs below that level. The upper border of the anæsthesia was distinctly in the region of the fifth intercostal nerve on the left side, on the right it was less accurately defined, but did not extend higher. All the symptoms agreed with those of tumors of the spinal cord, and the intense pain afforded ample justification for making an attempt to excise the tumor. Mr. Victor Horsley accordingly removed the spines and parts of the laminæ of the fifth and fourth dorsal vertebræ; but not until the third vertebra had been similarly treated did the tumor come into sight. It was a small oval myxoma compressing and making a deep impression on the left side of the spinal cord below the third vertebra. It was easily shelled out, and under careful antiseptic treatment the temperature did not rise more than 1° F. The wound healed rapidly, except at the uppermost point, where a drain had been left in by which a little cerebro-spinal fluid flowed away very slowly. For three or four weeks the former acute pain did not lessen, and even at times seemed more agonizing; but after that it gradually and intermittently decreased, and now, after seven months, is entirely gone; the sensation and motion of the body and legs are almost completely restored.

We join most heartily in the congratulations which the *British Medical Journal* extends to the operator in its account of the case, and trust that this first successful operation for spinal tumors may lead American surgeons to emulate their English brethren in attaining success in the management of these otherwise intractable cases.

SMALLPOX IN LODGING-HOUSES.

THE modern lodging-houses that are springing up in all our large cities deserve to be an object of special watchfulness on the part of the local health authorities, on account of the relations they sustain to winter outbreaks of smallpox. Some of our cities would be relatively free from that pest if the nomadic population which patronizes these cheap resorts could be legally held under sanitary surveillance and made safe by compulsory vaccination. A daily inspection would be advantageous to the community, in regard to many of these "hives" of impoverished and shiftless lodgers who, perhaps on the morrow, may carry infection to a jail, an almshouse, or a crowded steamer.

In Brooklyn, New York, the grand jury has just made a declaration censuring the authorities for failing to cause a weekly inspection of those "low-priced lodging places where temporary refugees, whose financial circumstances and migratory character forbid careful attention to cleanliness, congregate in large numbers." In the city above named, smallpox has been unusually prevalent this winter, and a very considerable proportion of the infecting cases have been traced to these cheap houses whose nightly population has been estimated to exceed five thousand persons, mostly tramps or persons but little superior to that class. Some of these places are so unsanitarily conducted that it has been said of them that all the vile odors of the town meet there once a week for consultation.

MEDICAL DIVISION OF THE PENSION BUREAU.

WE give on another page copies of two bills recently introduced in the House of Representatives affecting the medical officers of the Pension Bureau, and medical examining boards. The first bill increases the Medical Staff of the Pension Office by one surgeon and six medical examiners, and increases the compensation allowed to each class.

The salaries specified in the bill are certainly not too high, taking into consideration the amount of knowledge required and the importance to the Government of correct decisions by these officers.

The rates of compensation fixed by the second bill also seem low, and the only change which it makes is to give a little additional compensation to the Secretaries of Boards of Examining Surgeons, in consideration of the extra clerical work which they have to perform, a change which appears reasonable and just. We therefore hope that both these bills will become law, and if the Pension Examining Surgeons of the county interest themselves in the matter there is little doubt that this will be the case.

THE TREATMENT OF PULMONARY PHTHISIS BY CREASOTE.

IN THE MEDICAL NEWS of January 21, 1888, we called attention to the results reached by Sommer-

brodt and others by this method of treatment. Since that time we have had our attention called, by a kindly correspondent, to the fact that the formula, which was copied directly from the German, is not very clear. We have, therefore, hunted up the original formula used by Gimbert and Bouchard, which was also used by Fräntzel, and is given in his paper in the *Deutsche medicin. Wochenschrift* of April 7, 1887, as follows:

R.—Creasoti	. . . . .	13.5.
Tincturæ gentian.	. . .	30.0.
Spirit. vini rectific.	. . .	250.0.
Vini Xeric.	. . q. s. ad.	1000.0. M.

S.—A tablespoonful twice or thrice daily in a wineglassful of water.

As this formula is identical with that which Sommerbrodt states that he used, we hope that this note will not only serve to make clear the rather doubtful recipe first given, but enable our readers to put the method to practical tests and report their results.

Dr. W. T. Councilman, Associate Professor in Pathology in the Johns Hopkins University, has been elected to the Chair of Anatomy in this institution. The chairs of Chemistry, Physiology, Pathology, and Anatomy are now filled in this University, preparatory to the opening of the Medical Department.

Dr. Heneage Gibbes, late of Westminster Hospital, London, has arrived in this country, and has entered upon his duties as Professor of Physiology in the University of Michigan, Medical School, at Ann Arbor.

About fifty of the English laryngologists have signified their intention of joining a proposed British Laryngological Society; Sir Morell Mackenzie's name heads the list.

The first number of *The Brooklyn Medical Journal*, edited by the Editorial Committee of the Kings County Medical Society, has been received. The *Journal* is attractive in appearance, and the excellence of its contents and the ability of its Editorial Committee bespeak for it a place among our valued exchanges.

The *Journal of Reconstructives* became, on January 1, 1888, the *Dietetic Gazette*, and passed under the editorial control of Dr. George B. Fowler, and we understand that it is proposed to issue it as a monthly. The scope of the journal is indicated by its name, and the January number presents a very attractive table of contents.

The Methodist Episcopal Hospital of Brooklyn, New York, has just been opened, and the following medical staff has been appointed:

Consulting Physicians.—Alfred E. M. Purdy, M.D., Alex. Ross Matheson, M.D.

Consulting Surgeons.—L. Bolton Bangs, M.D., Nelson L. North, M.D.

Attending Physicians.—William H. B. Pratt, M.D., Benjamin F. Westbrook, M.D.

Assistants.—Warren C. Sneden, M.D., Glentworth R. Butler, M.D.

Attending Surgeons.—Lewis S. Pilcher, M.D., George R. Fowler, M.D.

Assistants.—John Bion Bogart, M.D., William M. Thallon, M. D.

Pathologist.—Eugene Hodenpyl, M.D.

Whooping-cough was very fatal in London during the last quarter of 1887, causing 828 deaths. This was one-third of the mortality by the chief zymotic diseases, or 2580 deaths, and about one-fortieth of the total mortality from all causes in that quarter, or 20,732 deaths. Scarlet fever, with 658 deaths, followed next in severity. In Salford, whooping-cough was unusually destructive of life. The same was true of Aberdeen and Glasgow, Scotland, also in Belfast, Ireland.

The *British Medical Journal* of January 28th, announces its weekly circulation at 14,500 copies; the figure having formerly been 14,000. It estimates that this total exceeds the combined circulation of all the other medical periodicals printed in Great Britain. This increase of 500 subscribers was subsequent upon a special issue of the *Journal* of December 10th, to the profession at large.

REVIEWS.

A Text-book of Therapeutics and Materia Medica, Intended for the Use of Students and Practitioners. By Robert T. Edes, A.B., M.D., formerly Professor of Materia Medica and Jackson Professor of Clinical Medicine in Harvard University. 8vo, pp. xi. 632. Philadelphia: Lea Brothers & Co., 1887.

The announcement some months since that this book was about to be published, was received with pleasure by students of therapeutics. The appearance of the volume will, however, disappoint their expectations, for the scope of the work does not fulfil their anticipations. The intention of making a text on materia medica is denied in

the preface, notwithstanding the title, and the directions for the use of drugs are too brief to prove satisfactory to the practitioner or student.

In the effort to condense, Dr. Edes has left out much matter which we believe it to be impossible to throw aside without great loss. As a good example of this we may mention the article on digitalis, the consideration of its physiological action and indications being not over two pages in length; aconite covers scarcely as much; while antipyrin and antifebrin cover, each of them, but a half page, or perhaps a few lines more. In addition to these disadvantages some of the statements made are, to say the least, calculated to mislead, if they are not absolutely incorrect, and vary so with commonly accepted belief that the author should have enlarged his text to defend himself. Thus, he states that the cumulative action of digitalis is that peculiar change which comes on when a person under the influence of the drug suddenly sits upright having previously been lying down, and that the "cumulative" action implies in no way whatever that any actual accumulation of the drug has occurred in the system. This statement, we believe, is not only contrary to the teachings of the best therapeutists of the day, but also to our knowledge, derived from both practical and experimental researches on the drug. Cumulative action is, we believe, generally recognized as being the result of the constant administration of digitalis, whereby, owing to its slow elimination, it accumulates in the body. This is particularly the case where kidney lesions are present, and where effusions of serum have taken place into visceral cavities. Under these circumstances sudden withdrawal of the effusion by tapping will often cause cumulative action by the absorption by the bloodvessels of the drugged liquids in the connective tissues. Cumulative action may, of course, come on from other causes, but it is often produced very suddenly by this means.

As we have already said, as a text-book it is far too meagre, and as a "Quiz Compound" it does not fulfil the requirements of such a doubtfully valuable sphere of medical literature.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 2, 1888.

THE PRESIDENT, A. JACOBI, M.D., IN THE CHAIR.

DR. ROBERT W. TAYLOR read a paper on

XERODERMA PIGMENTOSUM AND ITS RELATION TO MALIGNANT NEW GROWTHS OF THE SKIN.

It was in 1870, he said that Hebra and Kaposi published in their book the first account of a skin disease peculiar to childhood, multiform in its manifestations and indelible in its disfigurements. It was especially destructive to the eyes, nose, and mouth, and by its subsequent new growths was liable to lead to death. Their account of the disease was based on four cases observed by them. In 1877 Dr. Taylor read before the American Dermatological Association, at its annual meeting, a paper giving the histories of seven cases, all of which had been under observation for a number of years. At the same meeting Dr. C. Heitzmann also reported a case. In 1878 Dr. Taylor read a second paper on this subject before the Association, and the paper which he now presented to the Academy of Medicine, he said, embodied the results of his observations and studies for fifteen years.

In 1878 Duhring also reported a case, and in 1882 Kaposi published a valuable paper on the disease. In 1883 Neisser reported two cases, and embodied with their description an account of six cases observed by Rüder. In the same year Vidal's paper was published. In 1884 Pick published a paper, and in the same year Crocker also published one containing the histories of three cases, the only ones hitherto observed in England. In 1885 Kaposi reported his ninth case, and the same year Dr. J. C. White, of Boston, also reported one. Altogether forty cases had been observed up to the present time, but one of these had to be rejected as not being in reality an instance of the disease in question. There was more or less doubt about the diagnosis of some of the others, on account of the lack of a report of the earlier stages, but, notwithstanding the absence of certain data that were highly desirable, they were accepted.

Dr. Taylor then proceeded to give in detail the history of some of his cases. Three of them occurred in one family, and two of them in another family, closely related to the latter. All his cases were in females with one exception. In one of them, in which there were numerous vascular tubercular elevations, there was a supraorbital tumor of considerable size, which was operated upon by Drs. Gruening and Gerster, and later it was found necessary to enucleate the eyeball. The one boy who was the subject of the disease when seven years old was attacked with mumps, and, resulting from this there was an abscess, which had to be opened. The wound thus made never healed. Extensive ulceration followed, and this finally involved the coats of an artery, in consequence of which uncontrollable hemorrhage occurred, from which the patient died. Another of the children died of marasmus, and still another was accidentally drowned.

In these seven cases, Dr. Taylor said, all of the clinical features of the disease were portrayed. The affection consisted essentially of telangiectases, pigmentations, and atrophic changes; to which were superadded certain polymorphous new growths which were primarily benign, but were liable to degenerate into malignant tumors. In six of the cases the disease commenced when the children were about seven months old, and in the seventh at the age of fourteen months. The weight of evidence places this affection as one of very early childhood, and he laid great stress upon the prodromal erythema, the usual seat of which is on the face under the eyes, and which is liable to be mistaken for sunburn. It occurs in infants in good health and without apparent cause. This prodromal hyperæmia lasts from one to three months, and as it gradually disappears the pigmentations begin to make their appearance. They affect the face and the exposed parts of the neck and extremities; often extending as low as the third rib on the chest, and up to the elbows on the arms. They vary in size from a pin-head to a lentil, and are not much elevated above the surface. Scattered among them are the red or telangiectasic spots, in which congeries of capillary bloodvessels can be distinguished with a strong glass. Upon the hands there is much less of the prodromal

erythema than upon the face. In the meanwhile there are no marked local symptoms, heat, burning, and itching being absent; and the general health remains good. The lesions are always characterized by alternating exacerbations and periods of inactivity; so that the course of the disease is more or less erratic.

The period of the pigment spots and the telangiectases belongs principally to early childhood, and these two orders of lesions are peculiar to the stage of hypertrophy. The atrophic changes usually make their appearance at the end of the first year. The atrophy is not, as a rule, symmetrical, and varies greatly in extent and intensity in different subjects. It is not commonly as well marked on the extremities as on the face. This atrophy of the skin develops in accordance with the atrophy of the bloodvessels of telangiectasis. It is especially apt to affect the eyes, nose, and mouth, causing ectropion and deformity of the nasal and oral cavities. Very often hypertrophic changes are taking place at the same time as the atrophic. The career of the primary disease can then be briefly divided as follows: First there is, after a general hyperæmic stage, dilatation of capillaries; then these increase in size by new growth of their elements. This gives rise to the red spots, which contribute to the first stage of the disease. After remaining a variable period, these minute capillary new growths undergo atrophy, leaving on their site brown spots. This constitutes the second stage, while the third is occupied in the continual new growth of vessels upon the site of those already obliterated in the atrophy of the skin itself.

The pigmented spots, or pustules, are not necessarily permanent, but in certain localities, particularly where atrophy existed, they come and go, fading and being replaced by other similar spots. They vary in color from a light brown to black, and invariably appear in the exact positions previously occupied by the red ones, constituting a new function of the superficial capillaries. If these changes are carefully studied in any part, it is observed that a vessel first undergoes enlargement and becomes prominent, forming a red spot, and then it disappears by atrophy, the brown spot left partaking of the conformation of the usual spot.

The face presents a mottled appearance, and, in addition to the freckles and the red spots, there are found white spots ranging from a quarter of an inch to an inch in diameter. There is a want of elasticity of the skin, which is like parchment, or seems as if it had been coated with inflexible collodion. The appearance presented not unfrequently resembles the cicatrix of an extensive but superficial burn. There is an almost total absence of the normal secretions, and there is apt to be a peculiar immobility of expression upon the countenance. In some cases, however, the atrophy is much more marked than in others, and it is always less prominent upon the hands than upon the face. The atrophic condition is similar to that met with in senile atrophy of the skin.

While the atrophic changes are to be dreaded on account of their liability to result in deformity, the keratotic or warty patches which grow from some of the pigment spots are liable eventually to become malignant growths. There are two principal forms of new growths: (1) the keratotic; and (2) the larger, or elastic, which are, in reality, simply an exaggerated form of the first. Malignant new growths were recorded in 16 out of 30 cases, and non-malignant in 6 cases. In 9 cases in which there were as yet no new growths, 6 of the patients were under the age of twelve. Out of Dr. Taylor's own 7 cases, epitheliomata were found in 3. It is to be borne in mind that in any of the 6 cases with benign new growths, these growths might at any time become malignant. The statistics would seem to show that in this disease the greatest malignity is exhibited under the age of ten years; nearly as great between the ages of ten and twenty; and after that a diminished tendency to malignancy. It is certainly a singular fact, that epithelioma should develop in such young subjects. There was no evidence of metastasis in any of the cases.

Having remarked that it is impossible to give an exact description of all the tumors met with, Dr. Taylor proceeded to present the views of Kaposi, Neisser, and Pick in regard to the pathology of the disease.

The horny layer of the skin is thickened and desquamating, the stratum lucidum and stratum granulosum disappear, the Malpighian layer is thinned, and its deeper cells are strongly pigmented. The derma is atrophied; the papillæ are quite apparent, and certain masses of pigment are seen; numerous embryonic cells are met with, and a quantity of elastic fibres, which appear to have replaced the connective tissue to some extent. The vessels, the smooth muscular fibres, the sudoriferous glands, and the pilo-sebaceous follicles are diminished in number and tend to disappear. The fungous tumors usually present the histological character of epithelioma, and the most common disposition is that of a lobulated epithelioma with the fibrous stroma infiltrated with embryonic cells. In some instances the new growth was found to be of the nature of angio-myxoma.

Intelligent medication, extending over several years, had proved quite ineffectual, and no case of the disease had ever been cured. In the treatment measures should be taken to keep the skin at rest and free from all sources of irritation. All pigmentation warts should be removed as soon as possible with the spoon. All large tumors should also be extirpated, and the subjacent tissues thoroughly scraped, if necessary to the bone or periosteum.

In answer to a question from the President in regard to the absence of connective tissue, Dr. Taylor said that in this disease the papillæ are primarily involved, and the subcutaneous connective tissue only secondarily.

Dr. Jacobi then said that according to some authorities most, and to Cohnheim all, malignant tumors, occurring at any age, are the result of embryonic cells not undergoing the accustomed changes and remaining behind in normally developed tissue; and if this theory is to be accepted it will sufficiently explain the appearance of those malignant growths in early childhood. Furthermore, the fact that the bloodvessels are largely increased is no doubt the result of the embryonic tissue remaining; and these bloodvessels, it is to be noted, are not in a normal condition. He thought it probable that the occurrence of spontaneous thrombosis might explain the disappearance of the red spots and other phenomena noticed in the disease in question. On the whole, therefore, it seemed to him as if there was an arrest of the metamorphosis of embryonic tissue; and, if this were the case, he thought that in the treatment of this affection it might do good to increase the quantity of normal

connective tissue, if possible, and thus fortify the parts against the further development of abnormal growths.

For this purpose (provided the supposition mentioned was correct) there are two remedies which suggest themselves as preëminently indicated. These are, first, arsenic, and, second and better still, phosphorus. By the irritation excited by proper doses of these agents it seems possible to cause a good, solid normal nutrition to result. It is well known that phosphorus favorably influences the normal growth of bone, and for some years past he has used it with satisfactory results in caries and other bone disease. He has found it of special service in cranial rachitis. The phosphates or other compounds are of no value, and it is necessary to use phosphorus itself, administering it in oil or emulsion. It may be given in doses of one one-hundredth of a grain, corresponding to one minim of the old oleum phosphoratum twice a day, and its use maintained for a long period.

DR. TAYLOR, in conclusion, said that he thought these suggestions of the President very valuable and practical, and that if he should meet with another case he would institute a systematic course of medicinal treatment in accordance with them. At the same time, he thought the surgical measures to which he had referred in the paper were of decided benefit in controlling some of the more serious results of the disease; and contrary to what might perhaps be expected, he had found that, as a rule, the tissues healed well after the removal of the new growths.

CORRESPONDENCE.

PEROXIDE OF HYDROGEN IN THE TREATMENT OF DIPHTHERIA.

To the Editor of THE MEDICAL NEWS,

SIR: The most potent remedy for diphtheria is being entirely overlooked by the medical press and profession.

The peroxide of hydrogen will, in all stages of diphtheria, pseudo-membranous croup, and ulcerations of the mouth and throat, and stomatitis, act most admirably.

All physicians who have practised in districts periodically, or occasionally, visited by diphtheria, will recall the cyanosed condition of the little sufferer presaging death. Even after this condition plainly predicts poisoning of the blood by carbon the patient can be quickly relieved by fifteen or twenty drop doses of the peroxide internally, diluted with one or more tablespoonfuls of water. The throat should be gargled or swabbed with a solution composed of equal parts of peroxide of hydrogen and water, every half hour or oftener, or the solution may be used with an atomizer. All articles used for wiping the face or mouth should be kept sprinkled with the peroxide and all cuspidores or vessels should contain enough of the peroxide to destroy all germs contained in the sputa or excreta.

This remedy is not intended to supplant such auxiliary treatment as may be indicated, but will be found, used in conjunction with iron, potassium, stimulants, cardiac tonics, and nutritives, the nearest approach to a specific of any remedy heretofore used in diphtheria. Practical experience has made me rely on peroxide of hydrogen in diphtheria, and I earnestly ask that it be used, knowing that the results will be *startlingly successful*.

Yours truly,

WHITE BEAVER.

LA CROSSE, WIS., January 30, 1888.

THE CROWN PRINCE'S CASE.

To the Editor of THE MEDICAL NEWS,

SIR: Your issue of December 31, 1887, is just to hand, and I have been interested in reading the letter from Berlin contributed by Dr. F. Donaldson, Jr. In his remarks referring to my friend Morell Mackenzie's treatment of the case, he repeats some ridiculous stories, which have originated in the fertile German brain (but which are apparently still current in Berlin), as to Mackenzie not having permitted any German to examine the Crown Prince's throat until recently; and that Landgraf, who was sent to England with the Crown Prince, was also prevented from making examinations. To this statement I can give the most unqualified denial, and I scarcely think it can have originated with Dr. Landgraf himself.

From the time the Crown Prince came to England, to the time he left it, I was myself in daily attendance. I lived in the same hotel with him and with Dr. Landgraf until the Crown Prince left Norwood. Dr. Landgraf at first every morning, afterward whenever he chose to accompany me on my daily visit to the Prince, examined the Crown Prince's throat, for as long, and in whatever manner he pleased, and it is simple calumny to say that Mackenzie or anyone else prevented Landgraf from seeing the Imperial throat as often as he thought fit.

These matters are scarcely worth mentioning, except that they show the present animus of the German mind, which, for some months has, by a series of petty (or worse) vilifications, sought to damage Mackenzie. These attempts to sow the seeds of discord have met with a very receptive soil amongst a certain section of pseudo-Englishmen. The German nation has to thank Mackenzie for much. That their diagnostic powers are not infallible, they may not be prepared to admit, but may live to see. It is easy to understand that the course and prospects of the case are a hard pill to swallow, for what one of your American writers has described as "the vainest race in the world."

I am sir, yours, etc.,

R. NORRIS WOLFENDEN, M. D.

LONDON, January 26, 1888.

NEWS ITEMS.

The Water of New York Bay in its Relation to Cholera.—The *Weekly Assistant of Sanitary Reports* of February 3, 1888, issued by the Supervising Surgeon-General of the United States Marine Hospital Service, contains the following report of an analysis of the water of New York Bay, by Assistant Surgeon J. J. Kinyoun, Marine Hospital Service:

The cities and towns discharging their sewage into the New York Bay have an estimated population of 3,000,000 of people. In view of this fact, a chemical and biological examination of the bay water was undertaken, for the purpose of determining its contents, and also to find how

long it would support life of the different microörganisms, more especially that of Asiatic cholera. Accordingly, specimens were obtained at different places, being collected in sterilized flasks. The first was obtained at the Narrows; the second, alongside the steamship "Brittania" (lying in quarantine); the third, at Hoffman Island, and the fourth, at Swinburne Island. These different specimens were collected within thirty minutes, and just at incoming tide.

Chemical examination of one litre:

Narrows—	
Chloride of potash and soda	20.8 grammes.
Carbonates	A trace.
Iodine	"
Free ammonia	"
Albuminoid ammonia	0.158 gramme.
Steamship "Brittania"—	
Chloride of potash and soda	20.82 grammes.
Carbonates	A trace.
Iodine	"
Free ammonia	"
Albuminoid ammonia	0.158 gramme.
Hoffman Island—	
Chloride of potash and soda	21.64 grammes.
Carbonates	A trace.
Iodine	"
Free ammonia	"
Albuminoid ammonia	0.158 gramme.
Swinburne Island—	
Chloride of potash and soda	21.814 grammes.
Carbonates	A trace.
Iodine	"
Free ammonia	"
Albuminoid ammonia	0.158 gramme.

Reaction was slightly alkaline.

Plate cultivations were made from each of the different specimens, and at the end of five days had developed colonies of bacteria. Examination showing the number of microörganisms:

Narrows	4,500	to cubic centimetre.
"Brittania" anchorage	10,200	" "
Hoffman Island	9,600	" "
Swinburne Island	11,700	" "

The microörganisms found in each were several varieties of micrococci and one of a large bacillus. These were transferred to cultivation-tubes for further observation. On November 12, test-tubes, partly filled with sea-water, were thoroughly sterilized and inoculated in the usual manner, with pure cultivations of the spirilla of Asiatic cholera, and also of Finkler and Prior. Cultivation-tubes were inoculated from the water from day to day for the purpose of determining the longevity of the growths. During the first five days the water seemed to exert a slight inhibitory influence over their development. It was further observed that until January 20, a period of sixty-nine days, the characteristic growths of the spirillum of cholera Asiatica could be produced in peptone gelatine. That of Finkler and Prior has a yet longer lease of life.

Examinations made from time to time, both by the plate method and direct staining, show conclusively that these spirilla have not only been kept alive, but have also greatly increased in numbers.

After closely studying the currents of the upper bay, Dr. Kinyoun is led to believe that if dejecta from cholera patients should be thrown into the lower bay, cholera could gain a foothold on the contiguous shores, where every condition favorable to its development and propagation sometimes exists.

A Bill to Increase the Efficiency of the Medical Division of the Pension Bureau.—Mr. Burrows has introduced into the House of Representatives a bill by which it is proposed that the medical staff of the Pension Office shall consist of one medical referee, one assistant medical referee, three surgeons, and twenty-four medical examiners.

That the medical referee shall be a man of preëminent professional ability, and shall receive the sum of four thousand dollars annually. He shall be the chief of the Medical Division, and as such shall oversee and arrange the work of said division.

That the assistant medical referee shall also be of pre-eminent professional ability, and shall receive an annual salary of three thousand and six hundred dollars.

That the three surgeons shall be experts in their profession, and shall each receive an annual salary of three thousand dollars.

That the medical examiners shall be surgeons of education, skill, and experience, and shall receive each an annual salary of two thousand and five hundred dollars.

He has also introduced a bill to increase the efficiency of Boards of Surgeons for the examination of pension applicants, by which each member of each Board of Surgeons for the examining of applicants for pensions, shall, as now authorized by law, receive the sum of two dollars for the examination of each applicant.

That the Secretary of each Board of Surgeons shall receive a further compensation of fifteen cents for each examination.

That the Secretary of each Board of Surgeons shall be, and hereby is, empowered to employ a clerk, and for the official conduct and pay of such clerk the said Secretary shall be responsible.

The Restriction of Immigration.—A pregnant suggestion was made by Dr. John H. Rauch to the Illinois State Board of Health at its annual meeting last week. The veteran secretary, in discussing features of maritime quarantine, suggested that immigration be restricted by Congressional action, to those points where an efficient quarantine exists. This would be a good measure to carry out, but its ultimate effect would be still better. Let all the immigration to this country go to New Orleans, for example. How long would it be before diverging railway lines from New York City, and other commercial interests which feed upon immigrant travel, would demand, in unmistakable tones, that New York quarantine should be put in efficient condition?—*Sanitary News*, January 21, 1888.

The Children's Ward of the Presbyterian Hospital.—This most recent addition to the Presbyterian Hospital, of Philadelphia, was recently opened with appropriate ceremonies. The building and its equipments are the gift of Mrs. John Wanamaker. All which modern architecture and sanitary science could suggest have been done to perfect the structure, and in its appointments it is one of the best in America.

Hysteria and Malpractice.—At St. John's, N. B., suit was recently brought against a physician for malpractice, in producing convulsions by the administration, to a woman, of strychnia in doses of $\frac{1}{24}$th of a grain. The medical testimony for the plaintiff considered the dose as larger than prudence would indicate in the beginning of treatment by strychnia. The defendant asserted that the convulsions alleged to have followed the taking of strychnia were hysterical.

A verdict for the defendant was returned. The practitioners who testified varied in their doses of strychnia given from $\frac{1}{60}$th to $\frac{1}{12}$th of a grain.

Capital Punishment by Electricity.—Fell, of the Niagara University, Buffalo, has made a series of experiments upon animals to determine the possibility of resuscitation after the reception of a severe electric shock. He found such a shock thoroughly efficient, and gives his conclusions as follows:

First. That death, produced by a sufficiently powerful electric current, is the most rapid and humane of that produced by any agent at our command.

Second. That resuscitation after the passage of such a current through the body and functional centres of the brain, is impossible.

Third. That the apparatus to be used should be arranged to permit the current to pass through the centres of function and intelligence in the brain.—*Buffalo Medical and Surgical Journal*, February, 1888.

A Patent on Chloroform.—By a decision rendered in the United States Circuit Court of New Jersey the claim of the Albany Chemical Company is sustained, and the validity of their patent for the manufacture of chloroform from calcium acetate is established.—*Pharm. Record*, January 15, 1888.

Trichina in Ducks.—Twenty persons in Inoweal-law, Posen, were recently attacked with symptoms of trichinosis, and an investigation showed that they were poisoned by eating the flesh of trichinous ducks.—*Sanitary Inspector*, January, 1888.

The Fifth International Veterinary Congress will be held in Paris in September, 1889, under the presidency of Chaveau.

An Octo-centennial.—The University of Bologna will celebrate in June next the 800th anniversary of its establishment.

The London Medical Recorder.—It is announced that the *London Medical Record* is not to be discontinued, but transferred to a new business management, who announce its continuance under the same editors, but with a new name, and changes in its subscription terms calculated to adapt it to a more extensive circulation.

L'Electrotherapie is the title of a new journal devoted to electro-therapy, recently published in Paris. The editor in Léon Darion.

The Neglect of the Study of Medical Literature.—In a recent number of the *Berliner klinische Wochenschrift*, Virchow laments the disinclination of the present generation of medical students to study the literature of medicine. He contrasts the spacious reading-rooms, lighted by electricity, in use to-day with the narrow-windowed, inconvenient libraries of old, and urges the cultivation of literary study in men, who "at present cannot find time to go back even to Lænnec, in their literary researches."

Professor Scanzoni, of Wurzburg, has been placed on the retired list by his own request.

Dom Pedro, Emperor of Brazil, has been elected an honorary member of the Paris Society of Biology, in whose meetings he took a lively personal interest, when in Paris.

Professor Virchow will accompany Dr. Schliemann to Upper Egypt in the present month, remaining there until May.

Typhoid Fever in the Cities of Europe.—Among the cities of Europe the death rate from typhoid fever varies very much. According to Bertillon among 100,000 inhabitants there are in Vienna 14 deaths, in Stuttgart 15, in London 17, in Munich 18, in Brussels 19, in Paris 59, in St. Petersburg 90, in Marseilles, 149, in Barcelona 157, in Saragossa, 186.—*Sanitary Inspector*, January, 1888.

The Direct Gains of Sanitation.—In the town of Leek, England, with a population of nearly 14,000, the local sanitary inspector shows that in the last five years the mean expectation of after-life from birth in persons born in that town is 22 years more than it would have been had things remained as they were in the decade of 1851–61, when no real attempt had been made to grapple with the unhealthy condition of the town. Further, the actual money value to the community during the years 1861–85, from the increase of longevity and freedom from sickness, amounted from various sources to $433,900, which is equal to a direct saving of $17,356 per annum.—*Sanitary Inspector*, January, 1888.

Choosing Houses.—The *Sanitary Inspector* for January, 1888, quotes a journal of building as follows on this point:

In selecting a house, or a site for a new one, remember that where the sun will shine on the house for some hours a day one element of good is secured, especially if the sunshine enters at the windows of the living rooms or rooms most used during the daytime. After the aspect has been found to be suitable, and that a plentiful supply of sun and air is insured, attention should be given to the general position and construction of the house. If the ground is at all porous, a layer of concrete not less than six inches thick, and composed of cement or lime and broken bricks or gravel, should be spread over the whole of the ground covered by the building. This will prevent the passage of ground air up through the floors. Air will travel through the ground for some distance, and, as it invariably becomes contaminated by taking up carbonic acid gas in its passage, it is not suitable for inhaling. The house acts as a sucker on the ground, and if, unfortunately, the site is on "made" ground—that is, composed of all the refuse of a town—the ground air becomes the medium of disease. No houses should be built without a well-ventilated air space between the earth and the

ground floor, especially if the layer of concrete on the surface is omitted. The walls should be built of good hard-burnt bricks or non-porous stones set in lime or cement mortar. Common under-burnt bricks or porous stones hold moisture, which evaporates with the rise in temperature, and so chills the air in the house. If the bricks or the stones of the walls are suspected of holding moisture, the whole of the external surfaces should be covered with cement, or tiled or slated above. The foundations of the walls should rest on thick beds of concrete bedded in the earth; and to prevent the ground damp rising up the walls, a damp-proof course of slates, in cement, or a bed of asphalt should be laid in the full thickness or width of the wall just above the ground line. Dryness in this climate is so essential to health, that any building which in its floors, walls, or roof sins by admitting moisture, should be rejected as a place of residence by those who value their health. In tropical climates buildings are constructed to keep out the heat, but here we build to retain the heat and keep out the cold.—*Building*.

Christmas Gifts to the Crown Prince's Physicians.—The attending physicians and surgeons of the Crown Prince of Germany have not been neglected by their illustrious patient during the season of "peace and good will to all men" recently passed. For example, it is reported that Sir Morell Mackenzie has received as a present a valuable case of instruments; Herr Krause a diamond pin; Herr Schrœter two superb Japanese vases; Herr Bergmann twenty-four silver table ornaments; and Herr Schmidt, a gold inkstand. Apart from the intrinsic value of the gifts, it is quite possible to conceive that the possessors will treasure them as an earnest proof of the gratitude of the distinguished donor, on whose behalf their best efforts have been lately expended in order to avert distressing circumstances.—*Medical Press and Circular*, January 11, 1888.

The Electrical Treatment of Sewage.—The treatment of the enormous masses of sewage which pour forth from our large cities has for years been a problem, the solution of which has been attempted by means of series of very costly and more or less unsatisfactory experiments. At the present moment colossal works are in the course of construction for the precipitation of London sewage by the best known process, involving an expenditure of hundreds of thousands of pounds. Attention has just been called to a novel departure in the treatment of sewage. It has been discovered that the passage of an electrical current through it speedily generates enough gas to collect the solid particles into a scum on the surface, leaving the residual liquid clear and comparatively pure. Measures are shortly to be taken to test the value of this procedure in practice. Much as we are led to expect of electricity, from the disintegration of a fibroid to the removal of superfluous hairs, this, its last application, has the merit of novelty if nothing more.—*Medical Press and Circular*, January 11, 1888.

Carcinoma of the Larynx in Different Countries.—M. MOLLIÈRE, of Lyons, thinks that carcinoma of the larynx must be much more common in Germany and Italy than in France and England, for while he himself, though he sees annually some 7000 surgical patients, has never had a case suitable for extirpation of the larynx, and this operation is known to be a very uncommon one in France and in England, no less than 76 cases were mentioned at the Dresden Congress, and 101 operations are referred to in the Italian *Archives of Laryngology*.—*Lancet*, January 14, 1888.

Accident in a Chemical Laboratory.—While Professor Cazeneuve of the Faculty of Medicine at Lyons, France, was recently supervising a chemical analysis, the glass vessel containing the substance exposed to heat exploded with great violence. A small fragment of glass was driven into the eye of the Professor; it was promptly removed, and it is hoped that no serious damage will result. His face was also considerably wounded.

A Death from Neuralgia.—The *Lancet* of Jan. 7, 1888, reports the following case: Neuralgia, although one of the most painful maladies that the human race suffers from, has seldom been known to have proved fatal. A case, however, which occurred recently near Coagh, in the north of Ireland, would appear to have proved an exception. A lady suffered from neuralgia for forty days without any intermission of the pain, and it is alleged that she obtained no sleep during that lengthened period, although every means that medical skill could suggest were tried without effect. That the patient obtained no sleep for forty days is contrary to all physiological laws; but probably what sleep the unfortunate lady obtained was very trifling and inadequate, and it is most likely that death was due to the exhaustion occasioned thereby.

A Roman Sanitarium.—An important discovery has just been made at Suzo, about six miles from Castelforte, which points to the conclusion that the Romans were acquainted with the use of mineral springs for medicinal purposes. The erection of new mineral baths is contemplated by Signor Giuseppe Duratorre in that spot, and during the work of excavation the remains of what prove to be old Roman mineral baths have been met with. The buildings are situate about 250 feet from the right of the river Garigliano, which was formerly crossed there by a bridge, the remnants of a pier of which may still be seen in the river, and cover an area of 187 feet by 131 feet. A road paved with basaltic lava separates the two principal groups of buildings. To the left of this road, and leaning against the mountain-side, is the bath for hot mineral springs. The atrium is entered, as in classic dwelling-houses, through a portal adorned with columns, its floors being laid in black-and-white mosaic, and its roof probably formerly supported by four columns. Between these columns is the impluvium, a square marble basin, round which are seats, which leads to the supposition that it was used for bathing purposes. In the middle of the impluvium a hollow marble column supported a small basin of alabaster, into which the water rose through the column, flowing over its edges into the large basin. The further wall of the atrium opens into a large hall; through its side walls corridors lead into chambers to the right and left, the use of which for bathing is indicated by the whole arrangement of water basins and a network of water conduits, some of which are placed in the walls. On the outer side of the main road, with a view toward the river, two buildings are located, in front of which a row of columns with walled parapet probably enclosed a garden extending along the river bank. Between

the two buildings, containing rooms of various sizes, all of which open into outer corridors surrounding them, a colonade provided with seats has been erected. It is concluded that this group of buildings formed a hosptium or inn for the bathing guests—that is to say, a hostelry for those staying for their cure. The purpose of the whole establishment is also shown by the statuary found in a more or less damaged condition in the atrium. They include an Æsculapius, several female wall statues, and a statuette of a nymph, the upper part of the body nude, the lower draped. The marble of the statuary has been much injured by the mineral water, and its probable merit cannot, therefore, be easily estimated. Among the other finds a large cut amethyst may be mentioned, which contains in an oval two and a third inches by one and three-quarter inches a well-executed bust of a winged Nike. The sanatorium must have flourished for a long time, for, together with coins of Augustus's and Vespasian's time, Arabian and Norman gold coins have been found.—*Exchange.*

Great Brains.—The Paris correspondent of the *Lancet* of January 7, 1888, writes that at the Société de Psychologie Physiologique M. Manouvrier read a report upon the brain of the late Dr. Bertillon, the eminent statistician, and compared it with the brain of Gambetta, which has been studied by Mathias Duval and Chudzinsky. In weight Gambetta's brain was below the average, only scaling about 48 ounces. That of Bertillon exceeded the usual weight, reaching about 63 ounces. It is now admitted that, other things being equal, the weight of the brain is in proportion to the intelligence of the individual, and, moreover, the greater the intelligence the greater the absolute and relative development of the frontal lobes. A comparison of the brains of Gambetta and of Bertillon shows that the former is smaller, more particularly in the anterior portion, less so posteriorly, and that the temporal region is even larger. Now, the qualities of the two men were diametrically opposite. Gambetta was active and loquacious, Bertillon was reticent and retiring. Although an admirer of oratory, he had always failed as a speaker. In Gambetta's brain the convolution of Broca is extremely developed, in Bertillon's it is reduced to its most simple expression. Bertillon was in his youth left-handed, but he became ambidextrous later in life. The third frontal convolution on the right side (the speech centre of the left-handed) is larger than the corresponding one on the left side.

Female Medical Students at Zurich.—A professor of clinical medicine at Zurich, in a recent lecture, gave by his subject matter offence to his female hearers, they accordingly abandoned his lectures *en masse*. In return, the male students rallied to the support of their esteemed teacher, frequented his lectures and clinic, and addressed to him a formal expression of their sympathy.

It is evident that coeducation in medicine at Zurich is not without difficulties. Zurich affords, at present, the best opportunities to women of the centres of medical teaching on the Continent.

House Filters.—The *Lancet* Analytical Sanitary Commission has recently reported upon four kinds of filters, at present in the market. The tests made resulted in favor of the filter, whose essential portion was "spongy iron." Gas coke was recommended for trial as a filtering agent.

John Dean, M.D., M.M.S.S.—At the age of fifty-seven, this pioneer anatomist and microscopist of the nervous system died recently in Florence, Italy. He graduated from Harvard Medical School in 1860, and immediately completed microscopical researches upon the "Lumbar Enlargement of the Spinal Cord," and the "Gray Substance of the Medulla Oblongata and Trapezium," which were the first American researches in the minute anatomy of the central nervous system. His health, however, rapidly failed, and his later years were spent in hopeless invalidism. He generously gave his books, apparatus, and a choice collection of microscopic specimens to the Harvard Medical School.

Tito Vanzetti.—This distinguished surgeon, an octogenarian, died in Padua, on January 6, 1888. He had been for many years Professor of Clinical Surgery in the University of Padua, and had been the recipient of the highest honors. From his ample fortune he left $20,000 for the advancement of clinical surgery in his university.

ORIGINAL LECTURES.

KNOCK-KNEE AND BOW-LEGS, WITH REMARKS UPON RACHITIS.

Two Clinical Lectures Delivered at the Philadelphia Hospital.

BY A. SYDNEY ROBERTS, M.D.,

LATE SURGEON TO THE HOSPITAL, INSTRUCTOR IN ORTHOPÆDIC SURGERY IN THE UNIVERSITY OF PENNSYLVANIA, AND ORTHOPÆDIC SURGEON TO THE OUT-PATIENT DEPARTMENT OF THE UNIVERSITY HOSPITAL, ETC.

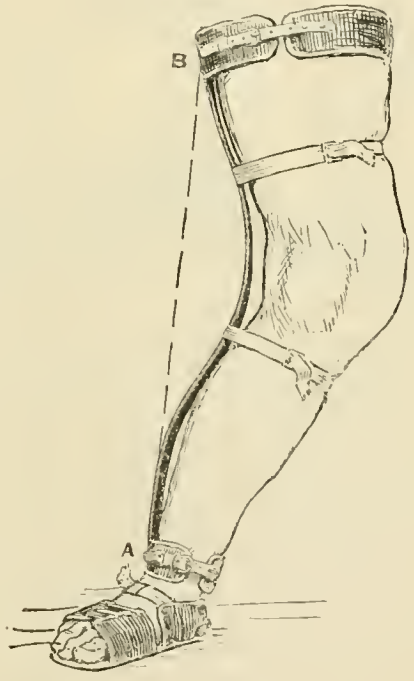
LECTURE II.

CASE III. *Knock-knee; application of elastic traction brace.*—Frances G. is two and a half years old, and has, as the father states, always been a weak, nervous child, and subject to croup. During the period of her dentition was much troubled by diarrhœa, and very thirsty; also perspired a great deal, and was restless and peevish. The ribs have the "beaded" feel; there is quite a prominent sternum, and all the epiphyses are flattened. The skull also shows evidences of rachitis. On placing the child on her feet, the deformity of the lower extremities, consisting principally of the in-knee deviation, is at once perceived. There is the usual extensive lateral motion at the knee-joints which is also manifested in the other articulations. When I flex the legs on the thighs, the deformity disappears; there is marked projection at the inner side of the knees, due to the hypertrophied internal condyle of the femur. The first thing that attracts attention to these cases is the peculiar gait when the children begin to walk, which they do not attempt, as a rule, until quite late, and, with this, much fatigue is complained of. Pain is not a frequent or urgent symptom, and, when it occurs, is referred to the inner side of the knee.

In the treatment of this case, the same rules should be followed as are applicable to the cure of bow-legs; and as sclerosis has not as yet occurred, I shall use, in addition to the retention braces to be worn throughout the day, an elastic traction brace at night. (Fig. 2.)

It is applied to the external aspect of the limb, and the upright extends well up to the thigh, and is secured at two points, just above and just below the knee-joint so that, in its efforts to right itself, it will produce continuous elastic pressure upon the *hypertrophied internal* condyle. It would be impossible in a clinical lecture for me to describe extensively the various forms of apparatus devised for the relief of this deformity, but among others used for removing it are those which aim at this result by the use of exaggerated interarticular pressure directed against the already hypertrophied internal condyle, thus attempting to produce absorption at this point. This also involves the use of intermittent rather than constant pressure. I am of the opinion that, while *intermittent traction* through soft tissues is of infinite value in the relief of certain deformities, this does not hold concerning intermittent pressure. Apart from the fact that these instruments are complicated and expensive, difficult of adjustment, and liable to constant malposition by slipping, etc., they must depend largely for their efficacy on the constant personal supervision of the surgeon or attendant. Again, the fallacy of attempting to produce absorption by intermittent pressure from without is clearly shown by Sir James Paget, in his "Lectures on Pathology," who, in speaking of atrophy as manifested in the Chinese foot, and also in stumps after amputation, says: "These examples, then, may suffice to show, as I have said, that constant pressure on a part produces absorption. Occasional pressure, especially if combined with friction, produces thickening or hypertrophy, and that these result whatever be the direction of the pressure."

FIG. 2.



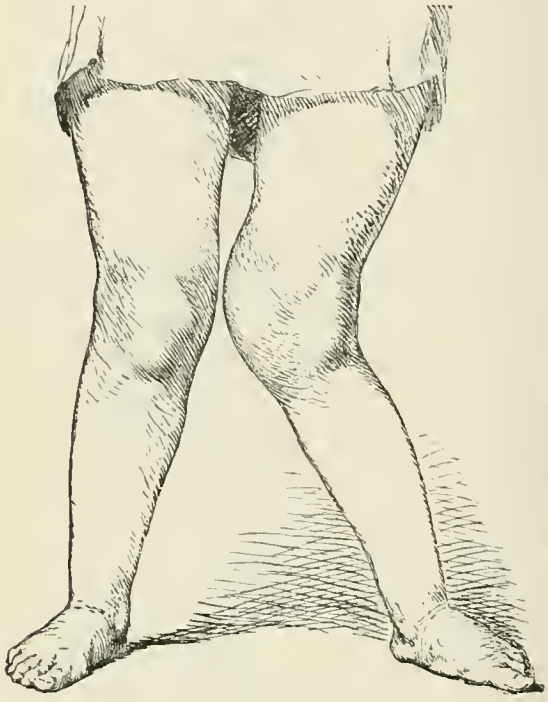
The positive atrophy and absorption of tissues from elastic pressure, on the contrary, are remarkably shown in the destruction and removal of large areas of bone, which frequently occur in aneurism of the aorta, and this brace is constantly exerting a similar influence upon the internal condyle.

CASE IV. *Unilateral genu valgum; osteotomy; cure.*—The next case is one upon which I operated at the clinic a few weeks ago, and is the first osteotomy for *genu valgum* performed at this hospital

Frank D., aged five, colored, an inmate of the children's ward, presented the following characteristic

rachitic deformities: The vertebræ are rotated upon their axes, and laterally deflected into the deformity of rotary lateral curvature and rachitic, the primary curve existing in the lumbar region. The deformity of the lower extremity presented as a unilateral genu valgum of the left limb. The femur is markedly curved in an anterior and lateral direction, the internal condyle being depressed below the normal plane of the joint, producing a decided in-knee deviation, as seen in Fig. 3, taken from a photo-

FIG. 3.



graph prior to the operation. The duration and pronounced character of the deformity apparently render this patient a fit subject for the operation of osteotomy or subcutaneous fracture of the bone for restoration of the limb to a normal position. Yet, in order to be perfectly sure that the stage of softening had passed, and that nothing more was to be expected from conservative mechanical treatment, I made use of the bone-drill spoken of, before operating, and finding all the indications of sclerosis present, I performed the operation of osteotomy, and am happy to show you the correction of the deformity as seen by these photographs, made prior and subsequent to the operation. (See Figs. 3 and 4.)

Before proceeding to the next case, I think it will be well briefly to call your attention to the different surgical procedures now in vogue for the relief of these deformities, and also to a short, historical account of them. These may be placed under three heads as follows:

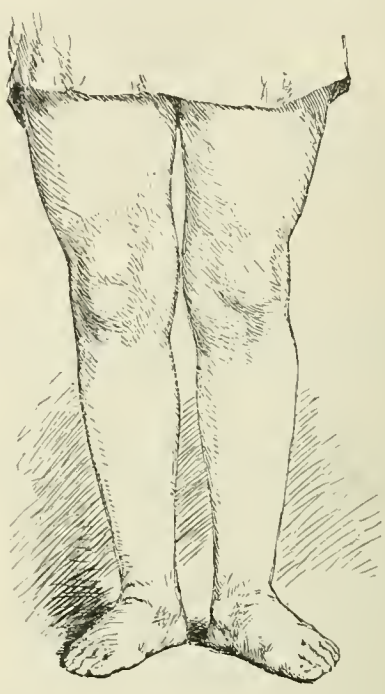
1. Forcible straightening.
2. Osteoclasis.
3. Osteotomy.

Of the first two mentioned methods, I will not enter into detail. They are approved by many surgeons, especially the French, and successful cases have been reported as having been brought about by these means; Delore, of Lyons, and Tillaux, being their principal advocates. Excellent osteoclasts have also been devised by Colin and Robin.

The brilliant results attained by osteotomy have, however, given this operation the palm, and most surgeons now perform this in preference to osteoclasis.

Although osteotomy for an ankylosed hip-joint had been performed by Rhea Barton, of this city, as early as 1826, it was not until 1852 that Mayer, of Hamburg, first operated for knock-knee. He opened the joint in his

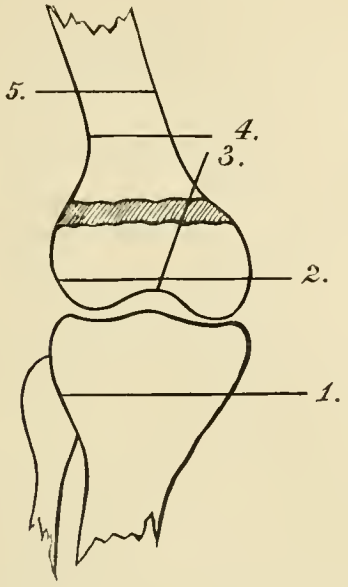
FIG. 4.



operation, and one of his cases died of tetanus. In the same year Langenbeck proposed osteotomy in cases of ankylosed knee. Following this many osteotomies of different articulations were performed, and American surgeons, Pancoast, Sayre, and Brainard, were among the first to practise them. As applied to the deformity genu valgum, the first operator in England was Annandale, who virtually excised a part of the condyles of the femur for knock-knee, the operation being done under antiseptic precautions. Antiseptic osteotomy was introduced by Volkmann, of Halle, in 1875, the same year that Annandale operated. In 1876, Ogston performed the operation, using the saw, and was followed by Schede, of Berlin. The objection to all these operations was the fact that the knee-joint was opened, exposing the patient to even a greater danger than the original deformity. In 1877 Chiene cut through the condyle with a chisel, removing a wedge-shaped piece. In 1878 Barwell performed his "simultaneous multiple osteotomy" which consisted in a division of both femur and tibia. In 1878 Macewen introduced his supracondyloid osteotomy, and this, involving no possible danger to the knee-joint, has been popularly adopted. In 1879 Reeves modified Ogston's operation so that the danger of opening the articulation was reduced to the minimum, the object being, at the same time, to replace the displaced condyle.

The following diagram (Fig. 5) will illustrate the various points of election for the performance of osteotomy.

Fig. 5.



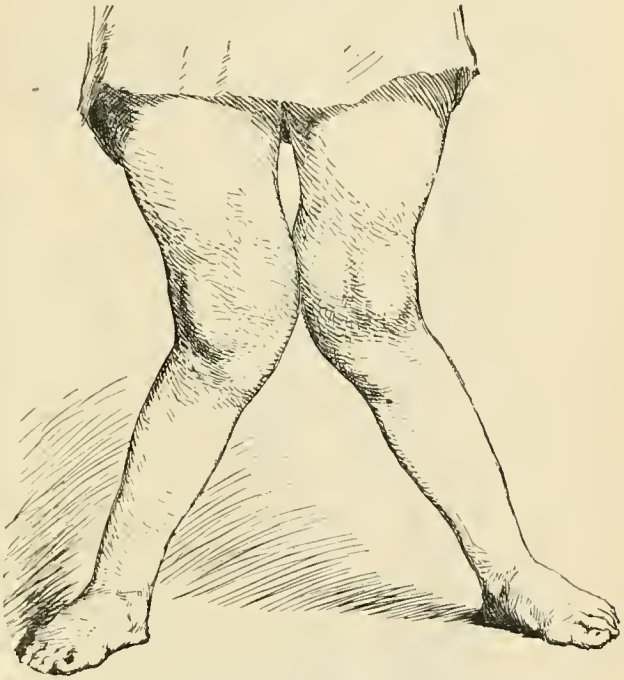
1. Mayer; Billroth; Schede. 2. Annandale. 3. Ogston; Reeves; Chiene. 4. Macewen. 5. Taylor.

Of all the operations mentioned, I give my personal preference to that of Macewen, and, in the case which I now present to you, propose to perform the operation.

Case V. *Bilateral knock-knee; double osteotomy by Macewen's method; recovery.*—The history in brief is as follows: Lottie H., aged five, colored, was admitted into the Philadelphia Hospital in 1881, suffering from severe bilateral knock-knee. No record could be obtained of her previous history, or the time at which the deformity first appeared. You will notice, however, that a marked curvature or in-knee deviation exists in both lower extremities (Fig. 6). The femora have an anterior bend in their lower third, as well as a lateral deviation. Curves of similar character are present in the tibia. On measurement, I find, when the internal condyles of the femur are approximated, the malleoli at the ankle-joint are separated nine and a half inches, as shown in Fig. 6, from a photograph. On account of the long standing and pronounced character of the deformity, having satisfied myself by the drill that sclerosis has taken place, I propose to do a double supracondyloid osteotomy, after the plan recommended by Macewen, of Glasgow.

The patient being anæsthetized, and having cleansed the limbs and rendered them aseptic at the point of election for the introduction of the osteotome, the elastic roller of Esmarch is applied, and the limbs rendered bloodless. After securing the vessels by a few turns of rubber tubing, the bandages are removed, and the limbs are ready for puncture, which is made at a point two fingers' breadth above the internal condyle. The osteotome is now introduced down to the bone, and turned transversely to the long axis of the shaft. By a few blows of a heavy wooden mallet, the instrument is driven through the bone, and then withdrawn from the wound, a little force being now required to complete the fracture. Now loosen the turns of the rubber tubing, to ascertain if any hemorrhage has taken place, and, as you see, this is very slight and mostly venous. The punctures are dusted with iodoform,

Fig. 6.

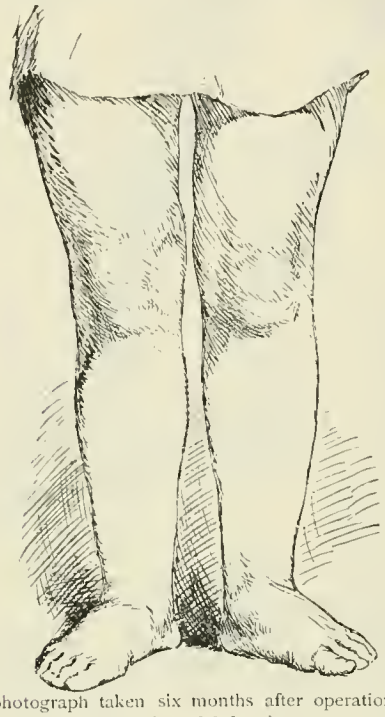


and covered with a pledgets of lint that have been previously soaked in compound tincture of benzoin, which quickly dries, forming an excellent artificial seal. The next step is to envelop the limbs in a flannel roller, and place over all the plaster-of-Paris bandage from the toes to the upper third of the thigh. It is well always to have the plaster thoroughly dried in an oven over night, as it facilitates its setting, and makes a much stiffer and more durable splint; while the plaster is setting, the limbs are "over-straightened," and the knees brought in a position of slight genu varum, by placing a roller bandage between them, and bringing the malleoli together. Three days from the date of operation I shall cut a small fenestrum in the dressing opposite the point of puncture, and examine the wound. Should no unfavorable symptoms intervene—*i. e.*, suppuration or retarded union—the dressing will be removed at the end of six weeks, and the patient placed upon her feet with light steel retention-braces, jointed at the knee and ankle, to allow of motion.

Before closing, I desire to say a few words upon the other causes of knock-knee and bow-legs mentioned in the early part of this lecture. Disturbance of trophic centres acting either upon muscular tissue, destroying equilibrium, or upon the nutrition of the epiphyses, has been assigned as a cause of knock-knee and bow-legs. The most direct results of central disturbance are seen in connection with poliomyelitis anterior (infantile spinal paralysis), and in tetanoid or spastic paraplegia. Here deformity is induced directly by the lack of supporting power in the muscles, as well as the loss of tone in the ligaments, and cannot be explained by the old antagonistic theory of loss of power in one set of muscles, with preponderating action in others. The same conditions obtain which Volkmann had shown to exist in the production of club-foot, the deformity not resulting from loss of muscular antagonism, but rather from growth whilst

the part remains in an abnormal position. It is also probable that in these paralytic cases the changes brought about in nutrition affect the bones to a large extent, as it has been shown that they are much thinner, more curved, and softer than normal. Here we cannot say that rachitis enters as an etiological factor, owing to the absence of its characteristic symptoms.

FIG. 7.



From a photograph taken six months after operation, showing correction of deformity.

The fact that cases of unilateral in-knee deviation are often observed without the association of symptoms denoting the presence of rachitis, has given rise to the idea that there is a condition which affects the nutrition of the epiphyses in such a manner as to produce knock-knee, and that this is a probable result of central changes having their expression in the epiphyseal cartilages of the knee-joint. This is purely theoretical, though not an entirely groundless idea.

I have thus endeavored to give you concisely the principal points in the pathology and treatment of bow-legs and knock-knee, and hope that, with the general indications I have attempted to impress, you will be enabled to cope successfully with these deformities.

ORIGINAL ARTICLES.

THE INFLUENCE OF OBESITY IN YOUNG WOMEN UPON THE MENSTRUAL AND REPRODUCTIVE FUNCTIONS.[1]

BY ANDREW F. CURRIER, M.D.,
OF NEW YORK.

IT is a matter of common observation that when a woman has passed the climacteric, or, in common terms, *the change of life*, a new era in her existence begins. As in the vegetable world, when the period of fruitage is passed, the foliage assumes luxuriant hues, and autumn becomes to us a synonym for bright colors and a restfulness of condition which tells of maturity and impending physical decay, so in woman we are accustomed to observe with the disappearance of the power of reproduction, the absence of menstruation (which is a normal accompaniment and customary evidence of that power), enlargement of figure, with particular tendency to the accumulation of fat upon the abdomen and the breasts, and the gradual development of mental repose, which is the more striking in those who have previously been characterized by restless activity, if not by mental and nervous disease and disorder.

The autumn of life in women more frequently presents these peculiarities than the corresponding period in men, though similar physical and mental changes in men do occur. It may therefore be considered the order of nature that mature life in women should mean the gradual cessation of the functions of menstruation and reproduction, and the development of obesity, and that there is a mutual relationship between the former and the latter, but that when they occur in young women they are unnatural, and an evidence, to a greater or less extent, of abnormal action.

To continue the simile from nature, young women in whom these conditions obtain are like a fruit tree which bears luxuriantly for a few years and then suddenly stops bearing, or like one which bears no fruit at all, but, instead, a vigorous growth of wood and leaves unless, perchance, new life is infused by judicious pruning and grafting. Of these two types, therefore, one is characterized by continuous child-bearing and lactation for a few years, four, five, or six children being born and suckled in as many years, sterility, amenorrhœa, and obesity following; in the other there is obesity, especially of the abdomen and breasts among married women, while in the young and unmarried the entire body is involved; there is also disturbed menstruation either in the form of amenorrhœa, oligomenorrhœa or dysmenorrhœa, and among the married there is either sterility or a single pregnancy.

The ancient writers including Hippocrates, Avicenna, Laurans, and Hoeflerus have recorded opinions which are in harmony with the foregoing statements,[1] and it is somewhat surprising that the

[1] Read before the annual meeting of the New York State Medical Society, February 7, 1887.

[1] Hippocrates considered obesity a cause of infecundity, and observed that it was also characterized by scanty and irregular menstruation. His theory as to the cause of sterility was that the *os uteri* closed by fat would not admit the semen. The scantiness of the menstrual fluid also signified the absence of a sufficient degree of intrauterine moisture to render conception possible. Complete works of Hippocrates translated (French) by E. Littré. II. 75. Quoted by Worthington: De l'Obesité, Paris, 1875, p. 56.

law which evidently obtains in this matter has been so generally overlooked by modern and contemporary observers; at least I have found very little reference to it in recent literature. That law may be formulated in the following terms:

1. A woman under thirty years of age who bears four, five, six, or more children in rapid succession and suckles them, prematurely reaches the limit of her physical powers as a reproductive animal, the phenomena of the climacteric supervening. This applies to the average woman under present conditions of civilization and, in a marked degree, to those who become obese after so frequent pregnancies.

2. A woman under thirty years of age who becomes obese, from whatever cause, will, as a result, be subject to amenorrhœa, or oligomenorrhœa (a term which I have proposed as a synonym for scanty menstruation), and usually to dysmenorrhœa, though menstruation may previously have been nearly or quite painless. If such patients be married sterility will be the rule. This law, like most other laws, has more or fewer exceptions, but observation and reflection during a not inconsiderable experience have convinced me of its existence.

Concerning the pathological anatomy of this subject, it is unfortunate that there are so few records of post-mortem investigations.[1]

None of the cases which have come under my observation have, as yet, terminated fatally. In most of them there has been heart weakness, which is particularly noticeable after any physical exertion, but I have never been able to detect more than a functional disturbance. In some cases there is not only a great increase in the volume of fat in those situations in which it is normally deposited, but the underlying muscular tissue is infiltrated, and this infiltration affects both voluntary and involuntary muscle. In the former I have seen it result in the separation of important muscles from their bony attachments, and it is these extreme cases, of course, which illustrate most forcibly the law which was enunciated. In the involuntary muscular system it is perfectly well known that the heart is susceptible to fatty infiltration, and it is probable, to say the least, in view of the clinical phenomena which are concerned, that similar changes affect the uterus.[2]

Schroeder divides the puerperal atrophies of the uterus into three varieties, the second being that which occurs after a normal labor and childbed with or without lactation in women of bad nutrition. Frommel[1] has seen 28 cases of this variety among 3000 cases of diseases peculiar to women. The patients were between nineteen and forty years of age, and showed no evidence of uterine or circumuterine inflammation. They suffered from severe abdominal pain, however, and atrophy of the tissue of the body and neck of the uterus, and of the vagina. The tissues were very soft, and easily penetrable by the sound. Frommel believed that in many women the uterus undergoes such excessive involution in consequence of lactation that subsequent restoration to a normal condition does not occur. He also believed that in cases in which a considerable number of pregnancies have followed each other in quick succession, the demands upon the genital apparatus have tended to produce permanent atrophy. Frommel's patients presented a "prematurely old" appearance. Whether this has any reference to obesity I cannot say, as the details of his cases are not given in his paper. The condition of the genitals, however, corresponds with that which I have observed in similar cases, and associated also with obesity.

Grigg,[2] in an article on "The Infantile Uterus," refers to a form of atrophy of the uterus and ovaries which occurs in early life as a sequence of parturition. He also states that a small and atrophic uterus may sometimes be found in well-developed women, associated with irregular, scanty, and painful menstruation. Atrophy of the uterus has been present in almost every case which I have seen which bears upon the subject. In fact, it was the repeated coincidence of uterine atrophy with obesity which drew my attention to the latter as a possible cause or factor in the production of the former. The length of the uterine canal in these cases has not been much less than normal, but the feel of the organ, both by the bimanual and the vaginal touch, is that of the uterus of old age, and the vaginal and cervical tissues are pale and senile in appearance.

The works of Möricke, Wyder, Leopold, John Williams, Putnam Jacobi, and a few others, during the past ten years, upon the endometrial mucous membrane and its functions has shown that sterility is usually caused by incompetency of that membrane to develop into a decidua, rather than by any fault in the ovaries and ova. A diseased condition of the endometrium with imperfect glandular apparatus and imperfect vascularization, together with a weakening of the muscular structure of the entire organ, would also account for scanty menstruation and dysmenorrhœa, all of which occur in the cases which are under discussion. It is to be regretted that the

[1] Worthington gives an account of an autopsy which was made upon a middle-aged woman who weighed nearly 400 pounds, but no examination of the uterus appears to have been made. The other abdominal viscera were abundantly supplied with fat. De l'Obesité, Paris thesis, 1875.

[2] It may be observed that the process of fat accumulation, according to Robin, involves the reception of that substance in emulsion in the fibro-plastic cells of connective tissue, contiguous to muscular tissue.

[1] Zeitschrift f. Geb. u. Gyn., 1882, vii. S. 307.

[2] Obst. Journ. Great Britain and Ireland, Feb. 1875, ii. p. 699.

evidence which is presented is only of a clinical character. Opportunities for more profound investigation may occur in the future; perhaps even this paper may stimulate some one who is better qualified than the writer to continue the investigation. With regard to the influence of displacements which might be suggested as coincident with obesity in causing sterility and dysmenorrhœa, I have seen no cases in which this factor entered, all the causative elements being physical rather than mechanical.

When sterility is present in these cases it is often the cause of great annoyance and unhappiness, even among those who have already borne several children. One of my patients was an Irishwoman, twenty-six years of age, who had borne six children in as many years, and was worried and unhappy because she had not become pregnant a seventh time. The maternal instinct was very strong, but she had become very fat; her uterus was atrophied, and the outlook for any further enlargement of her family entirely hopeless.

Two other patients were prostitutes who had never been pregnant. In one the uterus was atrophied, the menses had been entirely absent four months, and she feared that she was pregnant. In the other the uterus was nearly normal in size and appearance, but the menstrual flow was very scanty and pale, and she suffered with severe *backache* and *bearing down* pains, two or three days before the flow appeared, and during the two or three days of its continuance.

Another patient, twenty-six years of age, has been married three years, is sterile, and suffers with severe *backache* and *headache* before and during menstruation. The flow continues one day and is very scanty and pale. Coitus is painful, and there is an absence of sexual appetite, except just before the period, when it is exaggerated. Her uterus is small and hard, and she has occasional attacks of syncope.

A fifth patient is twenty-five years of age, married, and has been growing very stout for two years. She had a child three years ago, after a long and severe labor, and since then has been sterile. Menstruation recurs regularly, lasts three days, and the blood is ejected in clots. Severe pain in the back accompanies the discharge. Both the cervix and body of the uterus are atrophied.

A sixth patient is twenty-six years of age, has been married three years, has been pregnant but once, and did not carry the fœtus to term. When first seen she had not menstruated for three months.

In an interesting work on obesity, by Worthington,[1] the testimony of various writers as to the bearing of this condition upon menstruation and reproduction is summarized. Among this author's cases was one of a woman who became obese at the age of thirty-four, one year after the birth of her first and only child. In addition to sterility she suffered from irregular and scanty menstruation.

Glais[1] has recorded twelve cases in which obesity was mistaken by the patients for pregnancy. Amenorrhœa was present in almost all of them. Depaul[2] has stated that he has frequently been consulted by women who have rapidly become obese, especially upon the abdomen and breasts, under the supposition that they were pregnant. Amenorrhœa has been an accompanying symptom. Kisch[3] observed 208 cases in which obesity was associated with amenorrhœa or oligomenorrhœa, either as cause or effect. In many of the cases obesity was the only cause which could be suggested for the coexisting sterility. This testimony as to the correlation of obesity with disorders of the menstrual and reproductive functions warrants, in my judgment, the following statements with reference to symptoms: Sterility will be the rule, whether the patients have previously borne children or not. Should pregnancy occur, the impaired nutrition of the uterus will operate unfavorably upon its continuance to term. Should gestation be completed, it is not improbable that the offspring will be deficient in vitality, as has been demonstrated by Bunsen.[4] Menstruation usually occurs at regular intervals; several months may elapse between consecutive periods.

The quantity of blood which is lost during menstruation is almost always less than normal, and it lacks the character of normal menstrual blood. It is often only blood serum, containing a few epithelial cells. It may be expelled from the uterus in the form of poorly organized clots. The duration of the period may be a few hours, or a single day; I can find no record of its exceeding three days. It may continue a short time, cease, and after a few hours, or even a day or two, begin again, and continue another brief period. Pain is an almost constant symptom, beginning a few hours, or even several days before the flow appears, and continuing until the latter ceases. It is in the sacral region, in almost all cases. There is usually a sense of pain and fulness in the head. In particular cases there are *bearing-down*, or expulsive pains.

Vicarious menstruation has been observed in the form of nosebleed and bloody diarrhœa.

The sexual appetite is abolished in many cases, but in some it is quite pronounced during the few days preceding menstruation. Coitus is not infre-

[4] Neue Ztsch. f. Geburtsh., vii, 1, 1841: quoted by Worthington, op. cit.

quently painful. In one case, which was seen in consultation, there was acute hyperæsthesia of the entire genital tract, the patient having been under treatment for nymphomania. Such a condition of affairs is probably exceptional. The general condition is that which is common to those who suffer from adiposis, namely, impairment of the physical and mental powers, with disinclination to the performance of the ordinary duties of life. Constipation is almost always a troublesome symptom.

The causes which lead to obesity with its accompanying symptoms are usually discoverable, even if not always remediable. In most cases there is nothing peculiar about the process, the causes being such as would conduce to obesity in the opposite sex.[1] Among these may be mentioned an hereditary predisposition to obesity, derived from one or both parents, luxurious habits, sluggish disposition, an inactive life, excessive sexual indulgence, and the free or immoderate use of starches, fats, and sugar. An inordinate fondness for confectionery may be expected, as the rule. In those who assume obesity as a consequence of what may be called excessive childbearing, the causes may be considered identical with those which obtain when the climacteric occurs at the customary period, namely maturity of the physical powers, in so far as they appertain to the reproductive function, and diversion of the nervous energy from the sexual apparatus. My experience in this respect harmonizes with the views of Sir James Simpson and Frommell.

The prognosis in many of these cases may be considered exceedingly good, excluding, of course, those in which the climacteric has followed extraordinary fruitfulness. For the latter the condition of sterility is permanent, and I doubt whether any system of treatment could change it. It is the order of nature. For the others a properly regulated diet is of primary importance, hydrocarbons being eschewed in favor of albuminoids. Alcohol in any form is contraindicated. Suitable exercise must be insisted upon, either by the performance of the active duties of household life or a suitably arranged course of gymnastics, including *massage*. Worthington recommends[2] the systematic use of the waters of Vichy, Marienbad, Carlsbad, or Ems. I am profoundly impressed with the value of electricity for this condition both in the form of general faradization and the intrauterine use of the faradic current. Not only will the muscular tone of the uterus be improved by this means but the entire pelvic circulation will be favorably affected. I have seen some cases which seemed to be benefited by the use of astringents and stimulants to the interior of the uterus, also by moderate dilatation, but the same means have also been successful in exciting violent inflammation, which leads me to be cautious in recommending them.

The systematic use of laxatives will be required in almost every case, and we should look well to the condition of the heart, using suitable tonics as they are indicated. The internal use of iodine and its compounds has not been attended with the success which its early advocates would lead one to expect. Worthington approves highly of hydrotherapy, especially sea-bathing. Warm baths are, of course, to be avoided. As Worthington has suggested, it is not improbable that one who succeeds in relieving a patient of her obesity will, at the same time, cure her sterility, even without intrauterine medication, and this opinion is shared by Roubaud.[1]

159 E. THIRTY-SEVENTH STREET, NEW YORK.

[1] Manifestly an exception is made in those cases in which obesity follows frequent parturition and lactation.

THE OCCURRENCE OF COMA IN SUDDEN SPONTANEOUS BRAIN LESIONS.

BY WM. BROWNING, M.D.,
OF BROOKLYN,
LECTURER ON ANATOMY AND PHYSIOLOGY OF THE NERVOUS SYSTEM, AT THE LONG ISLAND COLLEGE HOSPITAL.

THIS symptom is one of the most striking and more frequent of those attending intracranial accidents. The absence of coma in some cases even of large cerebral hemorrhage, its occurrence in many cases of limited lesion, and often, but inconstantly, in cases of cerebral embolism are trite facts. No acceptable theory has been proposed to explain or harmonize these apparent discrepancies, and consequently the symptom has not acquired any definite clinical value. It is certainly permissible to attack such a problem in any way that presents, and whilst a complete explanation is not possible, yet it is believed that the symptom can be made clinically available for some classes of cases. Any study of the different forms and degrees of coma will not be attempted. For a brief definition of the term we may cite Gowers. "The prominent feature of apoplexy is loss of consciousness without obvious failure of the heart's action." In some cases consciousness is simply lost or clouded for a few moments; this can hardly be called coma. Often, unfortunately, our knowledge of the loss or retention of consciousness rests on very unreliable statements. Even careful observers may differ in what they call coma. It should be remembered that the symptom is a general ("diffuse") one, and may be produced by lesions on either side of the brain. "An apoplectic attack, coma, and also delirium, may occur without anything abnormal being found in the brain (or other part of the body) at the autopsy." Lesions of the cord, below the pyramids of the medulla, do

[1] Traité de l'impuisiance et de la stérilité chez l'homme et chez la femme, Paris, 1872.

not cause coma, though, if in the cervical portion, sudden death may result.

Suddenness of the lesion and increased intracranial pressure are acknowledged factors. Personal observation, and a study of the subject indicate that the seat of lesion is also an important factor. Evidently this view has never met with favor, though general opinions, for and against it, might be quoted. To determine its truth will be one of our objects, especially in view of the opposite opinion so positively adopted by such a recent writer as Wernicke. He assumes that a slower arterial supply, and freer venous discharge explain the slighter mental disturbance in hemorrhage into the mantel-zone. This factor of suddenness is, on the other hand, most prominent in embolism; hence, coma should follow embolism affecting this region, if his attempted explanation were correct.

There are three classes of cases that might come up for consideration, viz., hemorrhage, embolism, and thrombosis. Thrombosis and spontaneous softening may occasion loss of consciousness, but are of little value in this discussion. The rapidity with which the former develops, is variable and uncertain. Moreover, it often results from causes that affect the circulation in other parts of the brain, *e. g.*, atheroma, syphilis, neoplasms, and general exhaustive diseases. In many cases of (so-called idiopathic) softening, the rest of the brain is not entirely healthy; the softening represents what has become irreparable.

It is better to begin with the study of embolisms; because,

1. In them, one factor, that of increased pressure, is absent.

2. Their onset is more typically sudden.

3. The portions of the brain most frequently affected by them interest us first.

Embolism.

The effect of embolism on consciousness is considered less subject to rule than that of hemorrhage. The study of these accidents proves to us, however, that increased brain-pressure is not an essential or the only factor in the causation of coma.

There are a variety of matters which render it difficult to determine the effect on consciousness of an embolic insult to a given part of the brain.

a. The large amount of brain-tissue directly menaced in most cases. Even where softening follows, it does not often include the whole district at first deprived totally or partially of arterial blood.

b. It is questionable whether in all cases the artery is at once completely occluded. Wernicke thinks it admissible to assume this for most cases. However, this is not always true, and, when not, the shock or suddenness of the attack would be mitigated.

c. Many emboli soften and break up, thus either entirely disappearing, or only remaining in part in the shape of smaller emboli in terminal branches of the originally occluded vessel. When this happens early enough, softening is prevented, and we may have no permanent symptoms (no matter how severe the onset), and little or nothing to demonstrate, should the subject come to autopsy. Or, again, softening may have set in before the embolus was dislodged, when there would be nothing to show as the cause.

d. Another possible element of uncertainty lies in the usual co-lesion of the meninges, or at least some extent of the pia mater. The effect on consciousness of injury to this structure is doubtless slight.

e. In a goodly proportion of cases, embolism occurs in persons whose brain-circulation has been greatly weakened by preëxisting intrathoracic disease. In such, evidently, a much smaller shock might cause loss of consciousness. In reality it then appears very similar to syncope. The subject falls, if upright, but on being thus obliged to lie down, the circulation in a few minutes reëstablishes its equilibrium sufficiently to support consciousness, and the person revives. Such transitory loss of consciousness can hardly be called genuine coma.

A few opinions regarding the present subject may here be introduced, though rather to show the chaos of views that exists than for their real value.

Wilks (*Lectures*, p. 120) says:

"It might be thought that unconsciousness would be less likely to occur in embolism than in sanguineous effusion; but this is not always the case, for although it is true that there is often complete coma in large effusions from rupture of small vessels, as in ingravescent apoplexy, the unconsciousness and mental confusion are often less than in embolism."

Flint (reported in *Boston Medical and Surgical Journal*, 1879, vol. c. p. 668) says:

"From the long continuance of coma, we are justified in considering that the symptoms are probably not due to embolism, but rather to cerebral hemorrhage."

Wernicke (Bd. ii. 136) writes that

"Clinical experience shows unmistakably that isolated embolism of small vessels, up to the calibre of the largest perforating arteries, or the branches to Broca's convolution, does not usually suffice to produce unconsciousness and the fully developed apoplectic insult."

Sachs (*Journal of Nervous and Mental Diseases*, Aug. 1887, p. 507) states that

"It is well known that embolism is far more frequently accompanied by loss of consciousness than hemorrhage. The plugging of even a small cerebral artery is almost invariably followed by loss of consciousness."

Nothnagel (*Top. Diagnk.*, 1879, p. 612) holds that

"Observation teaches that in any localization whatever a hemorrhage may set in with loss of conscious-

ness, that, however, it may be absent in any [region], even in the cortex. There is no locality from lesion of which 'the apoplectic insult' must regularly be present or absent."

He adds that large hemorrhages and embolisms with extensive ischæmic districts produce a severe attack, though the converse is far from being as generally true.

Limits in the Selection of Cases.

It is necessary at the start to simplify the investigation as much as possible. In fact any successful study of the subject must largely depend upon the proper exclusion of irrelevant and misleading cases—a principle urged in another connection by Nothnagel in his "Topical Diagnosis."

1. All cases without autopsies are to be excluded.
2. All cases brought on by external shock.
3. All cases attended by convulsions.

Trousseau, *e. g.*, says that convulsions suffice to produce apoplectic stupor, and we have but to note the usual effect of an epileptic attack.

4. Many cases are poorly suited to our purpose, where the person has had a previous apoplectic or apoplectiform attack, is subject to epilepsy, is suffering from other nervous or severe bodily disease, or where there are bilateral or multiple brain lesions.

5. All cases where important particulars are wanting, *e. g.*, where the embolism occurred during sleep.

6. All where the subject was under twenty-one years of age. Children are known to be more subject to convulsions and coma than adults. Many persons certainly attain their development before twenty-one, but to exclude the element of infancy or youth this age has been universally adopted for other purposes and may well be for ours. Perhaps old age ought also be a ground for exclusion, but as senility does not come on with much regularity, such limitation will not be attempted.

7. In making what may be regarded as a primary study of the subject it is better to include only cases where the injury was limited to particular parts or structures. This is necessary before studying the results of co-lesion—even though partial—of two or more structures. As embolism but rarely affects any one of the basal ganglia singly we shall now take up only those cases where the embolic softening was wholly in the extraganglionic portion of the cerebrum (Mantelzone of the Germans).

Embolism of Sylvian (Middle Cerebral) Artery or its Branches.

From the seat of an embolism in this artery no sure conclusion can be drawn as to the exact portion of brain that will consequently soften. That an embolus in its more peripheral portions would rather cause a cortical and sub-cortical softening, and one in its beginning more often softening about the striated body, internal capsule, etc., is probable but in reality uncertain. This fact seems to have been ignored by most who have touched on the subject.

Hughlings Jackson says that in embolism of this artery "there may be no loss of consciousness and the hemiplegia may be transitory, though patients sometimes die in a few days in an apoplectic manner."

S. Mackenzie (*Brain*, 1878, iii.) writes that "most authorities agree that loss of consciousness is unusual in embolism of a Sylvian artery, though Niemeyer is a marked exception. Loss of consciousness may occur and be as complete as in severe hemorrhage, but this is unusual."

Nothnagel, holds that "while embolism of the Sylvian artery is, as a rule, attended with symptoms of apoplexy, yet it may occur without them," and Wernicke (ii. 136), that "embolism of the Sylvian artery before its bifurcation, or of one of its two chief branches, regularly causes a developed insult." He thinks that where this does not occur, we are to look for exceptional conditions (partial occlusion, etc.).

The accompanying table gives a nominal total of 32 cases (or 36 presumable embolisms), and includes all so far collected that come within the limitations laid down. No. 15 is insignificant. No. 32 occurred at night, in a patient with high fever. From complications and imperfect descriptions of the onset, several of the other cases are not entirely desirable; Nos. 15 and 32 may, therefore, be excluded, though they present nothing against conclusions drawn from those remaining.

This leaves 30 cases (not counting double ones) involving, one with another, a large part of the brain-mantle—a number sufficient to justify conclusions. Only in Nos. 7, 9, 18, and 26 was there any question of coma at the onset. The other 26 (resp. 30, separate embolisms) occurred without this symptom. In No. 7 a really comatose state did not develop—delirium from *second* attack. In No. 9, also, at *second* attack there was but momentary loss of consciousness—again not genuine coma. In No. 18 the short loss of consciousness (for ten minutes) is easily accounted for. The patient was in a fever, and one thoracic cavity was quite two-thirds filled by a recent effusion. The heart was slightly displaced, and the pulse weak. Moreover, the softening was beside the striated body—not superficial—and at first that structure may well have been implicated. This leaves but one, No. 26, amongst all the cases, that is exceptional, and even that is not necessarily so. It was presumably, though not certainly, due to embolism. There was bilateral cutaneous anæsthesia—absolute on the right, and nearly so on the left—of five days' duration. Five months later there was, for one day, a return of the various symptoms (at least aphasia, etc., and anæsthesia, though of a

29	Wilbrand,	Deut. med. Wchr., 1885.	M.	60	Described as an embolism.	White substance of occipital lobe shrunken, etc.	Thalamic and other foci from a later attack.
30	Haab,	Klin. Montbl. f. Augld., 1882 (*vide* Jour. Nerv. and Ment. Dis., 1886, pp. 18 and 22).	M.	68	Evidently embolic.	Cyst of softening in occipital lobe.	Onset not directly described.
31	Curschmann,	Centrlbl. f. Angkld. *vide* Frere, 1882, Obs. 60); also Rep. 7th German Cong. in Wien. Med. Wochr., 1887, p. 682.	M.	50	"of corresponding artery."	Cuneus.	
32[2]	Charcot,	Leçons, etc., Paris, 1872-3. pp. 72 and 74	M.	22	Posterior cerebral artery.	Nearly the whole occipital lobe.	Typhoid fever; whether the embolism caused or only accompanied delirium is not clear.

[1] The cases were not published as embolic. [2] Cases 28 to 32 inclusive, represent embolism of an occipital artery or branch.

different form). It was simply stated by friends that he had rolled his eyes, groaned, and lost consciousness for perhaps an hour. The peculiarities of this case may have been due to multiple emboli or an epileptiform complication.

There is also the possible explanation for any unusual case, that at first the embolus cut off vessels to the central ganglia. Hence, in 30 (resp. 32) cases, or in 32 (resp. 36) embolisms affecting only the brain-mantle, there is at most but one exception—and this doubtful—to the rule that embolism of this region in the adult does not cause coma. This is a result quite as uniform as other accepted facts in cerebral symptomatology. If, as proposed, all cases not described as embolic, and all not free from important complications, had been excluded, the uniformity would have been complete. But, for reasons already given, exceptions, apparent or real, will occur; it seemed, therefore, better to include the most probable so far found.

These cases do not, it is true, include all parts of the brain-mantle; yet they do cover about all that is often affected by embolism, or of which we have much knowledge, clinical or physiological. They extend over the whole period of adult life, from twenty-one to eighty-three years of age, and include both sexes (males, 20; females, 11; not stated, 1). The list presented makes no pretension to completeness, though cases satisfying the requirements are not plentiful. Bilateral embolism seems commonly, though not always, to cause coma. At least in Stewart's case (*Med. Times*, 1864, *v. Journ. Ment. Sci.*, 1868, p. 66), plugging of both Sylvian arteries, with resulting walnut-sized softening on each side, in

a man of twenty-one years, occurred without coma. Though this was presumably thrombotic, yet it indicates that the same might occur in embolism.

In any individual case, embolism limited to this region does not involve a *relatively* very large part of its whole, nor does it cut off tracts to other parts of the cortex (except, of course, association fibres). Hence it does not deprive of their function parts of the cortex not directly injured, and we have essentially symptoms confined to the part lost (ausfall-symptome of the Germans). If the area destroyed were sufficiently large—how large cannot be stated—there is no question but that coma would result; nor is there any doubt that lesions in this region have some tendency to cause coma. Only, in practice, embolism alone does not suffice.

Taking the cases as they stand, multiple attacks and all, delirium or some obscuration up to temporary loss of consciousness is noted in 5 out of 36 attacks. Lesser disturbances are very common. The present cases do not show whether lesion of different equal areas of cortex has or has not a like effect on consciousness, though destruction of sensory centres seems to be better tolerated.

Conclusions.

1. In adults free from relevant complications, embolism involving directly only extra-ganglionic portions of the cerebrum, does not cause coma.

2. Conversely, where the diagnosis of cerebral embolism is warranted, primary coma indicates implication of the basal ganglia or brain-stem.

3. The absence of coma does *not* preclude involvement of the said lower structures.

4. From the fact that more limited embolic injury involving other portions of the brain is frequently attended by coma, it follows that the location (or seat) of a cerebral lesion is one of the important factors in the causation of this symptom.

5. Wernicke's view, that the slighter disturbance of consciousness by hemorrhage into this region—as compared with hemorrhage into other portions of the brain—is owing to circulatory peculiarities, and hence to the absence of the factor of suddenness, is disproven.

6. Of course, thrombosis also, *under like conditions*, would not cause coma.

7. Whether embolism of the Sylvian trunk will or will not cause coma, is a useless question. It depends on the structures supplied by that artery in any given case.

8. It must not be considered that the above conclusions at all disprove the accepted view that the cerebral cortex is the seat of higher consciousness.

From the basis thus gained it will be possible to take up more intelligently the subject of hemorrhage into the same, and even other regions of the brain.

A CASE OF PENETRATING GUNSHOT WOUND OF ABDOMEN; NO VISCERA INJURED; RECOVERY.

By GEORGE S. BROWN, M.D.,
of Birmingham, Alabama.

B. C., white, æt. thirty-two, puddler by occupation. On December 2, 1887, about 12 o'clock noon, received a pistolshot wound of the abdomen from a 38-calibre Smith & Wesson revolver, at a range of ten or fifteen feet. Dr. Douglass, of this city, was called and found the wounded man where he fell. He administered a hypodermatic of morphia, and had the patient removed to his home two miles distant.

I saw the patient two hours later with Dr. Douglass. He was then comparatively comfortable, having suffered no noticeable shock. On examining the belly we found the bullet wound about three and a half inches to the right of, and on a level with the umbilicus. The direction of the wound was toward the median line and slightly downward. The thickness of the abdominal wall and the different conditions of contraction of the powerful muscles from that in which they were when the wound was received, rendered it impossible to say to a certainty that the ball had entered the cavity. The doctor ordered a two grain opium suppository, and we left him to get ready for an operation.

At 6 P.M. the pulse beat was 95, temperature 100°. At 9 P.M. pulse 110, temperature 101⅖°. At 12 M. pulse 130, temperature 103°, and all symptoms of an acute general peritonitis had set up. After consultation with Drs. Morris, B. T. Jones, Hargrove, and Douglass, and through the courtesy of the latter gentleman, I operated with the assistance of all. The wound was slightly enlarged, and under ether the track could be followed to its entrance into the cavity. An incision was then made in the median line from the umbilicus to the pubes, after shaving and cleansing the parts. All bleeding of any consequence was stopped before entering the cavity. The bowel was removed and carefully examined for wounds, being handled on towels wrung out of hot bichloride solution. After a thorough search of half an hour we failed to find any damage done, except the ragged hole through the parietal peritoneum, which was one and a half inches nearer the median line than was the external wound. No further trace of the ball could be found. Although the opening of exit from the cavity must have been there it was unavoidably overlooked. It could not be felt and the lamp we were working by did not give sufficient light to illuminate the cavity.

The visceral and parietal peritoneum was brightly congested, with minute patches of lymph deposited on their surfaces. About six ounces of bloody serum was sponged out of the cul-de-sac, and the cavity was then flooded with mild bichloride (1 : 6000) solution. The bowel returned, the cavity was again flooded and emptied, and then closed. A small rubber drainage-tube was left in the lower angle of the wound. A dressing of iodoform, absorbent cotton, and a roller was adjusted, and the patient put to bed.

The operation occupied from 12.30 until 2 A.M. The temperature was then normal, and remained so with the exception of a rise to 100° on the two evenings following. This was no more than might have been caused by another bullet which broke the patient's right arm.

The bowels were kept quiet with opium for six days, and then relieved with an enema. He vomited twice on the first day, but no stitches were ruptured, as the dressing had been tightly applied.

The dressing was removed on the fifth day, and the wound found to be entirely closed, except at the point of drainage and at two points between stitches where the skin had not been neatly approximated, these were granulating.

The wound was dressed again on the tenth day, when the drain was removed; and again on the fourteenth day when the sutures were removed. He was directed to wear a supporter for some weeks to lessen the danger of ventral hernia.

Aside from feeling it a duty to report cases, concerning which statistics are important, I think this case is of interest on account of its rarity—*i. e.*, a large size bullet passing through the peritoneal cavity and damaging nothing but its walls.

Dr. Morris's idea of its hugging the anterior wall from its entrance, and passing around and burying itself in the muscles of the left side (the man who did the shooting standing to the right and behind him) seems to me the only explanation; in view of the fact that he had eaten nothing for eight hours, the bowels must have been nearly, if not quite, empty, which condition, no doubt, was favorable to the harmless passage of the ball.

Still further interest attaches from the prompt arrest of the peritonitis through washing out the cavity.

Would the absence of shock indicate that none of the viscera was injured? Or was there absence of shock because the patient was heavily intoxicated when he received the injury?

DEODORIZED IODOFORM.

BY LOUIS GENOIS,
OF PHILADELPHIA.

Undeterred by the numerous methods already recommended for disguising the odor of iodoform, the writer ventures to suggest one more, believing it to possess in a marked degree the essential features aimed at—that is, complete concealment of the odor, and permanency.

The dissatisfaction with the disagreeable and persistent odor of the drug has become so pronounced that many physicians have discarded its use entirely, and have resorted to other bodies of an allied nature, in the hope that some of them would prove as efficient and reliable as iodoform.

The principal substitute employed, and that on which most dependence has been placed, is iodol, or tetraiodide of pyrrol; a compound which, from the large amount of iodine it contains, was thought to be equal, if not superior, to iodoform in antiseptic and alterative properties; from indications, however, which the writer considers conclusive, there is a well defined preference for iodoform among medical men, and if there could be devised some means of overcoming the objectionable odor, there is no doubt that the drug would reassume its incontestable supremacy.

Attempts to deodorize iodoform may be said to have been coeval with its introduction into medical practice, and perhaps it would be easier to enumerate the substances that have not been used for the purpose than those that have been recommended, so numerous and various are the latter. The essential oils, tannin (which decomposes the drug), coumarin, balsam of Peru (which abstracts iodine from its combination), ground coffee, charcoal, the alkaline carbonates, benzoic acid, etc., have each in turn been tried, and found wanting, either in permanency, or in causing a chemical reaction and changing the character of the drug.

Probably the best admixture that has come under the writer's notice is one of menthol and oil of lavender, a formula for which was published in a French journal, and was pointed out to him by Dr. S. W. Gross; but, as in other cases, in a week's time the added substances begin to volatilize, and the iodoform odor reappears, increasing in intensity until it is itself again.

The deodorant of which the writer advocates the use is purified naphthaline, to which a trace of turmeric has been added; this mixture will mask the characteristic odor so effectually as to challenge detection by the sense of smell alone.

The quantity of deodorant required to diguise the odor of a given quantity of iodoform is comparatively small; after a number of experiments, it was found that nine per cent. of the mixed substances was ample for the purpose. The following formulæ are suggested:

Deodorized Iodoform.

Purified naphthaline	7½ grs.
Powdered turmeric	1½ grs.
Iodoform	91 grs.

Rub together until thoroughly mixed.

Ointment Iodoform.

Deodorized iodoform (as above)	℥ij.
Oil of almond	℥ss.
Lanoline	℥vss. M.

Lanoline is suggested because possessing a strong odor of its own which assists in concealing the iodoform odor, and besides it is readily absorbed by the skin.

The deodorized powder can be used instead of the

simple drug in the making of suppositories, crayons, plasters, etc., and other preparations for external application. For making an ethereal solution the turmeric should be left out, as it is not soluble in ether.

1201 CHESTNUT STREET.

MEDICAL PROGRESS.

Creolin in Cystitis.—The *Lancet* of January 14, 1888, reports that in a very persistent case of cystitis occurring in a middle-aged woman, where the pain was so constant that the patient was generally obliged to keep her bed, and where the urine was offensive, brownish, and thick, depositing a third of its volume of pus, blood, and phosphates, after a large number of different kinds of treatment had been employed by various medical men without much result, the best application appearing to be injections of corrosive sublimate in very weak solutions, Dr. Jefsner, of Stolp, washed out the bladder with a half per cent. solution of creolin. This caused a burning sensation for a few minutes, after which it passed off. The next day the patient felt and looked quite a different woman, the pain in the bladder had been less than for a long period previously, and the urine, when drawn with the catheter, was scarcely offensive at all, and appeared quite clear, depositing after a time only a small quantity of phosphates without any admixture of pus or blood-corpuscles. The washing out of the bladder was repeated daily, and by this means the improvement was maintained. It would appear, therefore, that in creolin we a deodorizer and a hæmostatic, as well as a means of improving the character of the secretion from the surface of mucous membranes.

The Dangers and Uselessness of Very Strong Galvanic Currents.—At a recent meeting of the Paris Academy of Medicine, DANION stated that from his study of the effects of powerful galvanic currents, in experiments upon animals, he finds that they frequently produce severe congestions followed by inflammation of internal organs.

The electrolytic effects of moderate currents in gynecological practice illustrate the advantages of these currents. On the contrary, the use of very strong currents is equally harmful.

Very strong currents are absolutely useless.

Voltaic, non-caustic currents of great strength are apparently harmless, but further study is needed to confirm this opinion.—*L'Union Médicale*, January 19, 1888.

Methylal as a Local Anœsthetic.—LANGGAARD, in the *Therapeutische Monatshefte* for January, 1888, reports the following formulæ:

Methylal.	15 parts.
Ol. amygdal. dulc.	85 "

Also,

Methylal.	ʒ 2½.
Spiritus	ʒ 27½.
Ol. lavandulæ	gtt. 75.

to be used as liniments.

Methylal.	♏ 75.
Adipis	ʒ 7½.
Ceræ	gr. 45.

to form an ointment.

For application, upon cotton, to a hollow tooth.

Tinct. fol. coca.	ʒ 2.
Methylal.	♏ 30.

may be used.

The Relations of the Peritoneum to the Abdominal Wall, in Cystotomy.—STRONG, of Chicago, in the *Annals of Surgery* for January, 1888, reports the results of a number of experiments upon cadavers, as follows:

1. In the normal condition, the bladder and rectum being empty, the apex of the bladder and peritoneal reflection are a little above the arch of the pubes.

2. In moderate distention of the bladder the anterior peritoneal reflection is below the apex; with the same degree of distention and the bladder pressed against the abdominal wall, the peritoneum ascends higher.

3. Suprapubic cystotomy can be most easily and safely performed when the bladder is lifted from the pelvic floor and moderately distended against the abdominal wall.

4. Distention of the rectum alone elevates the base of the empty bladder, but does not raise materially the vesico-abdominal fold of peritoneum.

5. Distention of the bladder alone, in thin subjects particularly, requires relatively a greater amount of fluid to elevate the peritoneal reflection. The bladder is not crowded against the abdominal wall, but rather falls away from it.

6. Moderate distention of both rectum and bladder meets the indication the best; from ten to twelve ounces in the rectal bag and eight to ten in the bladder are generally enough, and seem to be a safe quantity to use.

7. Dilatation of the rectum first and the bladder afterward lifts the peritoneal reflection the highest.

8. The object of the rectal bag is to elevate the distended bladder and press it against the abdominal wall and so crowd up the peritoneum.

9. To meet the indication the gut should be dilated from the anus to near the promontory of the sacrum.

10. The rectal bag should be sausage-shaped, of rather thin rubber, rather than pyriform and thick, for the thinness enables it to follow up the gut, and the shape makes uniform pressure throughout the entire length.

11. In a very fleshy subject, with a flabby or pendulous belly, the bladder is relatively freely movable. In such a case it will easily rise out of the pelvis against the abdominal wall, when alone distended with a moderate quantity of water; the rectal bag may then be safely dispensed with.

12. Air, injected into the bladder of a subject, lifts the bladder and its peritoneal reflection out of the pelvis better than water.

13. In one case the gut was ruptured opposite the promontory of the sacrum with twenty-three ounces in the rectal bag, in no case was the bladder ruptured.

14. In the cases reported an average of fourteen ounces in the rectal bag and twelve in the bladder elevated the anterior peritoneal reflection an average of one and a half inches above the crest of the pubes; the apex of the bladder was one inch higher.

For Cancer of the Uterus.—The *Medical Press and Circular* gives the following formula for a suppository for use in uterine cancer:

Iodoform	10 grains.
Camphor	4 "
Extract of belladonna	1 grain.
Cacao butter	q. s.

For one suppository, to be placed in the vagina each night.

Cocaine in Operations upon the Eye.—In the *Archives of Ophthalmology* for December, 1887, Dr. Millikin writes as follows, regarding the use of cocaine:

A few words with reference to the use of cocaine in this connection may not be out of place. With a free use of a four per cent. solution the pain in this operation was not great, but still it was very perceptible. The great advantage from cocaine seems to be the obtunding of the superficial sensibilities of the cornea and conjunctiva; and this is the most important consideration, for operations on the deeper structures of the eyes are not, as a rule, particularly painful. A strabismus operation, even in a child, is borne without great complaint, while touching the cornea or seizing the conjunctiva, without the cocaine, with fixation forceps, is exquisitely painful. Recently I did an enucleation, in the case of a man with marked lung disease, with three or four instillations of a four per cent. solution of cocaine, and the pain complained of was only moderate, yet I have no idea that the cocaine affected in one way or the other the sensibility of the deeper structures cut through. Undoubtedly deep injections of the solution would further obtund the sensibilities, but I have not found this necessary, as I am able to do such operations as strabotomy, advancing the recti muscles, etc., without producing pronounced pain.

Rapid Reduction of Dislocation of the Shoulder.—Abril is quoted by the *London Medical Record* of December 15, 1887, as having employed the following method, with success:

In all the methods ordinarily employed for the reduction of dislocations downward of the humerus, the trunk is fixed and the head of the humerus is raised into the glenoid cavity. Dr. Abril inverts this proceeding; his plan is to fix the humerus and to make the glenoid cavity descend on to the head of the humerus. He claims for his method that it is most simple, easily, and quickly done, that chloroform is not necessary to obtain muscular relaxation, that the pain is trifling, and that no assistants are required. He makes the patient stand with a crutch in his axilla; he then holds the hand of the affected side, making slight traction downward; the patient is now to let himself down as if he were going to fall on his knees, and as he falls the head of the humerus glides into its normal position, and the patient is surprised at finding himself cured.

Strychnia as a Hypnotic.—T. Lauder Brunton, in the *Practitioner* for January, 1888, writes that in treating some cases of persons engaged in literary work who were suffering from sleeplessness and yet were obliged to have their brains perfectly clear during the day, it occurred to him that if he could convert the condition of over-tiredness into a condition of simple tiredness, the patient would naturally fall sound asleep without the use of any hypnotic. One can sometimes do this to a certain extent by giving some warm beef-tea or a teaspoonful of Valentine's meat juice in water either hot or cold, or by giving a little alcoholic stimulant, such as whiskey and water or brandy and water. It is probable that these substances have a double action, tending to dilate the vessels of the stomach and withdrawing blood from the head, as well as tending to exert what we may vaguely term a stimulant action on the nervous tissues themselves, without understanding what the exact nature of this stimulant action is. It occurred to him that as strychnine is one of the most powerful stimulants, if not the most powerful nervous stimulant that we possess, a small dose of it might have the effect of bringing the depressed nervous system up from the condition of over-fatigue to that of simple fatigue, and thus induce sleep. He accordingly tried it, and was much pleased with the result. It acted exactly in the manner that he expected, and induced comfortable healthy sleep without any disagreeable effects next day. The way in which he has used it has generally been either in the form of the tincture of nux vomica in doses of 5 to 10 minims or in the form of Schieffelin's granules, containing $\frac{1}{200}$ of a grain of sulphate of strychnine in each. One, two, or more of these granules were given at bedtime, and the dose was repeated if the patient happened to awake within one or two hours afterward.

The Odor of Iodoform.—Charteris, Professor of Therapeutics at Glasgow, reports the results of his studies in disguising the odor of iodoform as follows, in the *British Medical Journal* of January 21, 1888:

From a series of comparative trials I beg to offer the following prescription as securing the end in view:

R.—Iodoform	grs. 60.
Ol. amygdalæ	℥ijss.
Ol. theobrom.	℥ijss.
Ol. myristicæ	♏ xx.
Moschi	gr. iij.
Coumarin.	gr. vj.
Sp. tenuior	℥j.

The essential ingredient here is musk. To some people, however, the smell of musk is also disagreeable, and the other substances are added with the view of leaving a pleasant odor, neither of musk nor iodoform. If the iodoform is desired for dusting purposes, as in soft chancres or burns, the combinationof one grain of musk to ten or fifteen grains of iodoform is satisfactory. These prescriptions have been made up by leading pharmacists here, and they bear willing testimony to the facts mentioned.

Poisoning by Hyoscyamin.—Dr. Johnson, of Toronto, after reporting the case of a patient in whom one-twelfth grain of hyoscyamin produced serious effects, concludes:

1. That poisoning by hyoscyamin resembles, and may be easily mistaken for, poisoning by atropine.

2. That hyoscyamin is identical with "light atropine," "light daturine," and "duboisine."

3. That there are various preparations known as "hyoscyamin."

4. That these preparations differ exceedingly in their strength.

5. That there is a pure alkaloid hyoscyamin which should not be given, at first, in more than $\frac{1}{100}$ of a grain doses, and

6. That there is a resinoid hyoscyamin, commonly dispensed as "hyoscyamin," which may be given in doses of one-quarter to one grain.

7. That it is advisable for the safety of our patients, when prescribing hyoscyamin, to name the manufacturer whose drug we wish used. — *Canadian Practitioner*, January, 1888.

Quebracho in Dyspnœa.—Dr. Ellis reports, in the *Therapeutic Gazette* of January 16, 1888, that he has found the following formula useful:

R.—Syr. prun. virg.,
Syr. tolutani,
Ext. quebrach. fld. . . āā ℥j.
Acid. hydrocyanic. dil. . . gtt. xxiv.
Morphiæ sulph. . . . . gr. jss.—M.
Ft. sol.

Sig.—Take a dessertspoonful as often as necessary to afford relief.

After the first two doses, each containing two-thirds of a drachm of the quebracho, the difficulty of breathing was very considerably reduced, the respirations sinking from 46 to 24 per minute in three hours, and by continuing it according to direction the patient was enabled to enjoy a longer period of comparative ease than she had experienced for months.

Stimulants and Narcotics in Skin Diseases.—In the *Dietetic Gazette* for January, 1888, Fox, of New York, writes as follows:

One very important point to be considered in preparing a diet list for patients with skin disease is the effect of alcohol, tea, coffee, and tobacco in retarding tissue-metamorphosis. To improve the nutrition of the skin, it is desirable that the processes of waste and repair be carried on without cessation. When alcohol or other stimulants are consumed to any extent this desirable change or reconstruction of tissue is arrested, and the various organs of the body are impaired in the performance of their functions. The effect of beer upon an eczema is as marked as it is upon a gonorrhœa, and I have sometimes thought it better for a patient to drink a whole bottle of whiskey than a single glass of malt liquor. The effect of tobacco and coffee is frequently seen in cases of pruritus, and in private practice I have fallen into the habit of forbidding all stimulants on the ground that they do no good and may do harm. In charity practice it has often struck me as the height of folly to prescribe medicine for patients who are living largely on tea and beer, and whose symptoms would speedily disappear under a judicious regulation of diet. Indeed, it is difficult to appreciate what dietetics will do in the treatment of cutaneous and other diseases unless we move, for the time being, a suspension of the Pharmacopœia.

Sulphibenzoate of Sodium.—This new antiseptic is described by Heckel, in *Comptes Rendus CV.*, p. 896, as prepared by dissolving sodium benzoate in a strong solution of sodium sulphite. It is said to be very soluble in water, and to be absolutely innocuous to human beings, even if taken in large doses. It has been tried in the Hospital of Saint Mandrier, and it is reported as the result of the clinical experiments conducted there, that a solution made by dissolving a drachm in a quart of water, is superior to carbolic acid as an application to wounds, and that it may be compared in value to the salts of mercury without having their poisonous properties, or to iodoform without its disagreeable odor. The physical and chemical properties of the compound have not yet been published.—*Provincial Medical Journal*, January 2, 1888.

Guaiac in Scarlatina.—Dr. Armstrong, of Detroit, relates his experience in the use of guaiac as follows:

In the following sixteen cases since treated with this remedy, including four of a very severe type, it has not disappointed me in a single instance, though I did not always use it to the exclusion of other medicines when they were indicated. Where constipation and scanty secretion of urine occur, I know nothing better than the pulv. jalapæ co., given in large enough doses to produce free evacuation of the bowels. When the headache is intense and the temperature is high, in the commencement of the attack, I combine with the guaiac, aconite in small doses, often repeated. And when the guaiac is prescribed alone the results are better when given frequently, *in small doses*, deing due, perhaps, to its local effect. Another point of no small importance, as the disease is one occurring mostly in children, is its agreeable taste, when combined with simple syrup, or elixir. The fluid extract is the only preparation of the drug I have used, although the tincture, or the ammoniated tincture, might be equally effective. The formula most often prescribed has been:

R.—Fld. ext. guaiac . . . . ℥ ij.
Tr. aconit. . . . . ♏ vj.
Syrup . . . . q. s. ad. ℥ ij.—M.

Sig.—One-half a teaspoonful every two hours, for a child one to two years old.

This dose might be increased or the medicine given oftener, though I have not found it necessary to give it in large doses. It is taken without the addition of any water, as a rule, so as to get its best local effect.—*Medical Age*, December 26, 1887.

Strophanthus in Russia.—Dr. A. Kazem-Bek, of Kazan (*Vratch*, Nos. 40 and 41, 1887), relates seven severe cases treated by tincture of strophanthus (one part of the seeds to ten of alcohol), five drops being given every three hours, four times during the first day, and ten drops three times daily subsequently. The cases included chronic myocarditis, with consecutive cardiac dilatation, with calcareous deposits on the aortic valves and walls; mitral stenosis, with regurgitations (two cases), alone or complicated with parenchymatous nephritis; bronchial asthma, with pulmonary emphysema (two cases); aortic stenosis, with regurgitation; and cardiac neurosis in a hystero-epileptic woman. In only one case, that of a woman, aged thirty-seven, with rheumatic mitral disease and chronic nephritis, did the drug partly fail, and, even in that case, it proved beyond all comparison better than succinate of caffeine and sodium, or digitalis with valerian, or grindelia robusta, or convallaria, with which the lady had been successively treated before. In the remaining six cases, strophanthus produced a striking improvement, usually in a very short space of time; dyspnœa ceased; the paroxysms of bronchial or cardiac asthma, as well as œdema, gradually disappeared; the

heart's action became much less frequent and more regular, and the pulse fuller and stronger; while the daily amount of urine considerably increased. When taking the medicine, the patients slept soundly and quietly for many successive hours. This circumstance is attributed by Dr. Kazem-Bek partly to an improvement in their general state, but partly to a direct sedative action of the drug on the brain, since a drowsy condition was observed by him also in dogs after an intravenous injection of the tincture. The experiments on animals (frogs, turtles, and dogs) were undertaken by the writer mainly with the object of elucidating the question whether strophanthus acts solely on the muscular tissue or not. He has come to the conclusion that the drug acts, not only on the cardiac muscle itself, but also on the cardiac ganglia and peripheral endings of the vagi. This conclusion is based on the following facts: 1. That atropine gives rise to a considerable acceleration of the heart's contractions which have been previously slowed by strophanthus; and 2, that strophanthus does not slow the heart's beats which have been previously accelerated by atropine. Dr. Kazem-Bek has also found that strophanthus increases the blood-pressure, but this increase seems to be independent of the heart's contractions; at least the arterial tension continues to rise, while the number of the beats remains unchanged.—*British Medical Journal*, January 21, 1888.

Lanolin a Prophylactic Against Bacteria. — Gottstein, of Berlin, after numerous experiments, has found that lanolin is not decomposed by the agencies commonly destroying fats, and that the integument, when it has been thoroughly applied, is much less likely to admit poisonous germs and materials than otherwise.—*Therapeutische Monatshefte*, January, 1888.

Pulmonary Tuberculosis in a Cat.—Filleau and Léon Petit, in the *Journal de Médecine de Paris* of January 1, 1888, report the case of a cat, frequenting their laboratory and clinic room, which devoured eagerly the sputa from phthisical patients.

Well-marked symptoms of pulmonary tuberculosis developed, and the animal seemed losing ground rapidly. On the intervention of pregnancy the advance of the tubercular disease was checked; pregnancy went on to term, and a litter of well-formed, apparently healthy kittens was born. The mother continued in comfortable health until she was bitten by a rabid dog, several months after confinement, when she was immediately killed.

Caseous tubercular matter and bacilli were found in the lungs; tuberculosis was latent; the other organs were healthy.

Urethan. — This hypnotic, introduced by Schmiedeberg, has been found useful in insomnia from cerebral hyperactivity; in the adynamic insomnia of neurasthenia; in heart diseases; in phthisis. It does not control pain; it is unreliable in the excitability of alcoholism. It may be used in mental diseases, where mania is not too violent; it speedily loses its effect through the patient becoming accustomed to it.

In full doses it checks convulsions caused by strychnine.

Its dosage is from 15 to 30 grains; hypodermatically from 7½ to 15 grains.

It may be prescribed as follows:

Urethan	℥1½.
Aq. destill.	℥15.—M.

Sig.—Dose, 1 to 2 teaspoonfuls.

Huchard prescribes, for children:

Urethan	℥1.
Aq. destill.	℥10.
Syr. aurant. cort.	℥5.—M.

Sig.—Teaspoonful at half hour or hourly intervals, until sleep is produced,

And

Urethan	gr. 3.
Aq. flor. aurant.	℥10.
Syr. simpl.	℥5.—M.

Sig.—A child's teaspoonful hourly.

—*Deutsche medicinische Wochenschrift*, January 5, 1888.

Hæmatoma of the Larynx.—Ter Maten, in *Wiekablt voor Geneesk*, 1887, i. p. 679, reports the case of a teacher who had suffered from hoarseness for five years, which he referred to a severe cold.

Laryngoscopic examination showed a bluish-red tumor on the left vocal cord. When grasped by forceps it collapsed, ejecting a quantity of blood. The tissue which had covered it was easily removed.

Erysipelas of the Auricles following Piercing of the Lobes.—Dr. Thorner reported at a meeting of the Cincinnati Medical Society three cases of erysipelas of the auricles, originating from the habit of piercing the lobes. One occurred in a child, whilst the other two were those of adults. The erysipelas spread in all cases over face and scalp.—*Cincinnati Lancet-Clinic*, Feb. 4, 1888.

Spontaneous Detachment of a Laryngeal Polypus.—At a meeting of the Berlin Medical Society, December 21st, Prof. Fränkel read a very interesting communication from Sanitätsrath, Dr. von Swidersky, of Posen, on a case of extrusion of a polypus of the larynx during the act of coughing. Dr. von Swidersky had known the patient, a cavalry officer, since 1848. In 1862 he began to be affected with hoarseness and dyspnœa, and Dr. Valentiner then diagnosed laryngeal polypus. Other authorities in Berlin and Tübingen were consulted; one of these was of opinion that villous cancer was present, because the growth (plainly visible on the posterior third of the left vocal cord, and attached to its inferior aspect) bled profusely when touched. All who were consulted advised tracheotomy, but this the patient would never hear of. The dyspnœic attacks occurred from time to time, often accompanied by severe hemorrhage, and the hoarseness increased. In 1870, von Swidersky, tracheotomy being still refused, attempted local treatment. The tumor was first touched with caustic potash (well solidified), and afterward daily with a concentrated solution of ergotin. On May 12, 1870, the patient was in imminent danger of suffocation, but next day his medical attendant found him in good voice and spirits, enjoying a cigarette with his coffee. He triumphantly pointed to a substance which he had coughed up, and which he had placed in water. Microscopical examination showed that it was a fibroid polypus. The patient has remained well since then, and

there is only a slight inclination to laryngeal catarrh. V. Swidersky attributed the cure to the ergotin treatment. Professor Fränkel had never in his large experience met with a similar case, and was of opinion that practically we should never trust to such a lucky termination, quite as uncertain as the chief prize in a lottery. But he had seen a case in which a polypus had very gradually retrogressed. Dr. Böcker had independently diagnosed the existence of a polypus in this case, so that there was no doubt about it. Hensch thought that it might have been coughed up without the patient's knowledge, and argued from analogous rectal polypi in children, but Fränkel persisted in his opinion that the improvement in his case had been but gradual, and promised further details in a paper on the subject about to appear.—*British Medical Journal*, January 21, 1888.

Iodoform in Antiseptic Gynecology.—POZZI has used the following fluid for impregnating gauze:

Iodoform	ʒ12½.
Glycerin.	ʒ25.
Spirit. vini.	ʒ21⅞.

Iodoform suppositories may be prepared with

Iodoform pulv.	ʒ5.
Gummi arab.	
Glycerin.	
Amyl.	āā gr. 30.

—*Le Progrès Médical*, January 7, 1888.

Fatal After-effects of Chloroform.—DR. UNGAR has recently published in the *Vierteljahrschrift für gerichtliche Medicin* an account of some researches which he has made in order to determine precisely the effects of chloroform on the tissues. He kept a large number of rabbits and dogs under chloroform for many hours, with intervals of suspension of the anæsthesia. After death, marked changes were discovered in the tissues. The muscular tissue of the heart was very fatty, and numerous points of fatty degeneration were found in the endocardium. Similar fatty changes were found in the epithelium of the larynx, trachea, bronchi, pulmonary alveoli, and gastro-intestinal tract. The epithelium of the convoluted tubules of the kidneys was either full of fatty granules or was in process of breaking down. The liver cells and the epithelium of the smaller biliary ducts were affected in a similar manner. Fatty changes were also detected in the striated fibres of the diaphragm, and, though less marked, in the rectus abdominis and the extensors of the thigh. In nearly every case these appearances were most marked the longer the animal had been kept under chloroform. Dr. Ungar observes that the animals were healthy, whilst in the case of patients fatty changes due to illness, cachexia, alcoholism, etc., often exist before the narcotic is given. In such a case the chloroform may do much harm even when the patient recovers. Some of the animals died more than twenty-four hours after coming to from the final dose of chloroform. Dr. Ungar is therefore induced to believe that death shortly after operations may be more often due to the narcotic than is generally supposed. His researches do not confirm Nothnagel's theory that the fatal action of chloroform consists in the disintegration of the colored corpuscles of the blood. He believes that the anæsthetic acts directly on the chlorine and chlorine salts diffused through the tissues. The successful administration of chloroform during labor, to which Dr. Ungar refers, appears to prove that the anæsthetic acts less seriously in our species than in animals, yet his paper contains important suggestions which should not be overlooked.—*British Medical Journal*, January 14, 1888.

Formulæ for Eczema.—BROCQ, in the *Revue Gén. de Clin. et de Thér.* of January 12, 1888, has collected the following formulæ for the treatment of eczema, from various authors:

Cold cream	ʒ 7½.
Glycerine	ʒ 2.
Oxide of zinc	gr. 30.
Tinct. of benzoin	gtt. 15.

Also,

Tannin	gr. 30.
Calomel	gr. 15.
Glycerate of starch	ʒ 7½.

Salicylic acid may be combined as follows:

Acid. salicylic.	gr. 8 to 30.
Zinc. oxid. pulv.	
Amyl. pulv.	āā ʒ 6.
Lanolin.	ʒ 7½ to 10.
Vaselin.	ʒ 5 to 2½.

Boric acid ointment:

Acid. boric. pulv.	gr. 30 to 90.
Vaselin.	ʒ 7½.
Balsam Peruv.	♏ 8.

Mix; add

Acid. boric. pulv.	gr. 75.
Adipis or vaselin.	ʒ 2½.
Lanolin	ʒ 8¾.

The Treatment of Warts by Arsenic.—PULLIN describes among others, the following case illustrating the value of arsenic in treating warts:

Minnie P., æt. four, I happened to see while attending her mother in a confinement, and was struck by the peculiar appearance of one of her little fingers, the ungual phalanx of which was apparently the seat of some abnormal growth, being irregular and bulbous; on closer examination, however, it proved to be nothing more than a crop of warts, which almost entirely covered the nail. On the same hand there were many others, and likewise on the opposite hand. After taking liq. arsenicalis, ♏j, for ten days, most of the warts had fallen off, and those which still remained I easily removed with my finger and without the slightest pain to the child. Several other cases, in which I have treated these unsightly and troublesome growths in the same way, I could record, but in every instance the cure has been complete and rapid; and I think the above case in itself alone proves the value of arsenic for treating warts; for it is certainly equally rapid in action, and moreover has the great advantage over the caustics in being painless, which is of so much importance in treating young children.

Creasote Hypodermatically in Phthisis.—ROSENBUSCH, in *Wiener med. Presse*, No. 3, 1888, reports good results from vegetable creasote in almond oil, three per cent., injected beneath the skin in the second intercostal space, or the supraspinatus fossæ. He intermitted the treatment in pauses of two or three days.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, FEBRUARY 18, 1888.

SUDDEN DEATH IN TYPHOID FEVER.

MONNERET has said, with less sacrifice of the truth than is usual in epigrams, that "typhoid fever includes all pathology." It may be also said that its terminations illustrate every manner of dying. In the twelve or fifteen cases that prove fatal in every hundred of the disease, death comes in various forms—slowly, by gradual asphyxia or progressive adynamia; rapidly, by intestinal perforation, acute peritonitis, profuse hemorrhages, or nervous accidents; suddenly, by processes not yet fully understood. This last mode of termination is not the less important because of its comparative infrequency. It is a calamity neither to be foreseen nor prevented, and must, therefore, interest us practically as a misfortune possible in any case; theoretically, as a problem in the pathology of typhoid fever yet awaiting, nay, now urgently demanding solution. To its consideration DEWÈVRE has recently devoted an elaborate and important article in the *Archives Générales de Médecine* for October and December, 1887.

Cases of sudden death in typhoid fever from obscure causes were recorded by Louis, Chomel, Andral, and others in the second quarter of the century; later, Virchow, Zenker, and Wunderlich published many observations concerning this accident, but it remained for Dieulafoy, in 1867, to ascribe to the subject its due importance, and to furnish an hypothesis as to its cause. Since then, Griesinger, Hayem, Laveran, Longuet, Jaccoud, Tripier and a host of others have published cases. Dewèvre estimates the proportion of sudden deaths in typhoid at four per cent. of all fatal cases. This estimate, based upon French military statistics, is certainly higher than an extensive knowledge of the disease, as seen in hospital and private practice in the United States, would warrant us in making. It is most common about the age of twenty-five, rare in infancy and after forty. There appears to be no constant relation between the debility and constitutional feebleness of the patient and this accident, which very frequently befalls young and vigorous subjects. It is of more frequent occurrence in military than in civil life. As regards the period in the evolution of the attack in which this accident is most likely to occur, it is toward the close of the illness and especially in the third week. It is of more frequent occurrence in cases of moderate severity than in those which are on the one hand grave, or on the other, mild. Dewèvre has succeeded in collecting only four cases of sudden death in typhoid relapse. Like other peculiarities of the disease, it is met with in varying frequency in different epidemics.

The administration of carbolic acid, sodium salicylate, or quinine in large doses has been regarded as predisposing to sudden death. The method of Brand has especially been accused of determining to this unfortunate issue by the violence of the perturbations which it excites in the organism. It is certainly true that sudden death has often occurred at the moment of some movement on the part of the patient, or of some unusual emotion. On the other hand, many of the cases have occurred in sleep. There is nothing in the history of the cases that will enable one to foresee this accident. Dyspnœa has been observed; syncope and convulsions may occur. Even at the moment of death, the symptoms are without significant characteristics. Very often the patient simply grows suddenly pale, sinks back, and dies before the attendants can render assistance. When symptoms occur they are of nervous origin, intense dyspnœa, angina, spasmodic cough, convulsions, sometimes limited to the face and upper extremities, sometimes general.

In a large proportion of the cases the necropsy fails to reveal lesions adequate to explain the sudden death. There are the characteristic lesions of typhoid: nothing more. In other instances the anatomical changes are significant. We find granular

and fatty degeneration of the heart, proliferative endarteritis of the branches of the coronary arteries, pericardial effusion, in many cases doubtless due to the death agony, endocarditis, heart-clot, embolism of the pulmonary artery. The lungs are often intensely congested, and there may have been bronchitis or pneumonia. The condition of the brain is by no means constant. There may be intense congestion, or, on the other hand, in many cases its substance has presented an extraordinary paleness. Alterations of the kidneys are present in by far the greater number of cases.

Dewèvre reviews the various theories of the mechanism of sudden death in typhoid fever with great acumen. The theory of pulmonary embolism, that of thrombosis of the heart, that of degeneration of the heart muscles, that of obliterative endarteritis and cardiac ischæmia are carefully examined, and each in turn rejected as inadequate. So with the ingenious theory of intestinal reflex proposed by Dieulafoy, and that curious theory of stomachal reflex of Tambareau, and that of cerebral anæmia, and the theory of uræmia and that of overwhelming typhoid intoxication. Each may serve, according to the views of its advocates, best to explain cases or even groups of cases, but no one of them is generally applicable.

Sudden death, such as is here described, is a special accident of typhoid fever closely associated with the anatomical changes peculiar to that disease. It comes only in one of three ways: the patient succumbs to one of the common causes of sudden death, as hemorrhage, embolism, and the like; he dies of uræmia due to the nephritis of typhoid fever; or life is destroyed by special localization of the infecting principle upon the pneumogastrics.

URINE FEVER.

Mr. Reginald Harrison, of Liverpool, devotes most of the first Lettsomian lecture, which is published in the *British Medical Journal* of January 7, 1888, to the consideration of urine fever. We are all familiar with the phenomena of rigors and fever which sometimes follow surgical procedures upon the male urethra, and which are usually spoken of as urethral fever. Harrison considers this term to be inappropriate, since the febrile manifestations are not dependent upon any peculiarities of the urinary passages, but upon the contact of urine with a wounded surface, where certain poisonous products are generated, and by their absorption produce the well known symptoms. As these symptoms are entirely due to the contact of the urine, he denominates them, urine fever. His argument is very suggestive, and carries much weight with it.

The anatomical structure of the urethra is such that it is water-tight, the urine passes over it, but does not come in contact with an absorbent surface; when, however, a catheter or other instrument is introduced the epithelium is liable to be detached, and then rigors and fever frequently supervene; of course, the danger increases with the amount of injury to the tissues, hence, prolonged instrumentation, internal urethrotomy, and other serious procedures are not infrequently followed by urethral or urine fever. That this fever is due to the absorption of toxic substances from the urine is proven by the fact that, if the urine is withdrawn by suprapubic aspiration, and whilst the bladder is empty, the same manipulations are performed, no fever will result, because urine does not come in contact with the raw surfaces.

Noticing the infrequency of these phenomena after lithotomy and incisions into the bladder, where the urine flowed freely over the wound but was not retained in it, Harrison arrived at the conclusion that fresh urine is incapable of originating this fever, and that a pocket or sac into which urine can be collected and undergo decomposition, is essential. In order to verify this, he performed first internal urethrotomy and then perineal section on the same person in several cases, and introduced a drainage tube into the bladder, and in none of them was any urine fever produced.

Again, there was immunity to a great extent in those who were placed under the influence of large doses of quinine, the explanation being that it acted as an internal antiseptic and to a large extent sterilized the urine and rendered it innocuous. This result also followed the injection of sublimate or boric acid solutions into the bladder. He considers the poisonous product to be a ptomaine, which develops as the result of heat and moisture.

The following summary represents his views upon the etiology of urine fever. 1. That the presence of urine in relation with a recent wound is necessary for the development of urine fever. 2. That the mere contact of urine with a wound is not sufficient for its production. 3. That the retention of fresh urine within the area of a recent wound is almost invariably followed by its development in a greater or less degree. 4. That where urine is placed under

such circumstances as have been last mentioned, the liability to the development of urine fever is greatly diminished when it is sterilized by local or general means. 5. That the retention of fresh urine, blood, and the débris of damaged tissue in the confines of a recent wound for a certain time at a temperature of somewhere about 100° F., could hardly be possible without chemical changes taking place in the constituents referred to. 6. That there is a common origin for urine fever is rendered probable by the uniformity of the symptoms attending it, which, though different in degree, are identical, whether following a surgical operation or an accidental wound.

ANTIPYRIN AS A HÆMOSTATIC.

Although this youthful drug has been already recommended by various practitioners for almost every disease to which human flesh is heir, but lately still another application has been found for it. Byvalkevitsch reports in *Vratch* his experiences with antipyrin in stopping hemorrhage, and states that doses of twenty to eighty grains arrested hemorrhage during phthisis, even when ergot had failed, and he lauds it considerably in consequence.

Henocque, at a recent meeting of the Société de Biologie, called attention to this use of the drug (*Gazette Hebdomadaire*, January 13, 1888), and to the fact that he proposed this remedy in 1884; that Arduin and Huchard had reached similar conclusions concerning it; and that Casati, in Italy, Goltz, in Switzerland, and several others have confirmed this belief.

The difference between the methods of Henocque and Byvalkevitsch consists in the fact that Henocque uses a powder or an ointment of antipyrin, while Byvalkevitsch gave the drug internally. How it is possible for a drug which affects the circulatory system as slightly as does antipyrin, to arrest hemorrhage when taken internally we fail to see, and unless the method of Henocque retards hemorrhage mechanically it is useless; even if this be the case, it is unnecessary, in view of more easily used and more valuable methods.

At the annual meeting of the New York State Medical Society, held at Albany last week, the following were elected officers for the ensuing year:

President—Dr. S. B. Ward, of Albany.

Vice-President—Dr. A. Walter Suiter, of Herkimer.

Treasurer—Dr. C. H. Porter, of Albany.

Secretary—Dr. Wm. Manlius Smith, of Syracuse.

Censors—Southern District: Drs. J. S. Warren, of New York; W. B. Chase, of Brooklyn; W. H. Helm, of Sing Sing. Eastern District: Drs. Joseph Lewi, of Albany; Thompson Burton, of Fultonville; L. McLean, of Troy. Middle District: Drs. Henry Flood, of Elmira; Robert Frazier, of Camden; I. N. Goff, of Cazenovia. For Syracuse University: Dr. I. N. Goff.

Committee of Arrangements—Drs. E. L. Partridge, of New York; F. C. Curtis, of Albany; and C. S. Merrill, of Albany.

The New York Academy of Medicine has called the attention of the Board of Health to the practice of druggists to dispense filtered water for distilled water. An investigation was ordered, and samples of water were obtained from twenty-five prominent druggists, only one of which was distilled. The other samples were filtered Croton water, containing more or less organic impurity, sufficient in many instances to impair the efficiency of the prescribed solution. This substitution of filtered for distilled water is held to be an adulteration, which is punishable by a fine of fifty dollars for the first offence. The druggists have received warning that proceedings will be taken against those who in the future are found guilty of this form of substitution.

For the furtherance of female medical education in India, prize-funds have been inaugurated by the Countess of Dufferin and others. The first prize of the Dufferin-fund has been claimed for a student of the Grant Medical College at Bombay. Sir Walter de Souza has given the Calcutta Medical School a trust fund of two thousand rupees, additional to former donations, to aid the female students of medicine who repair to that school of the Indian metropolis.

The municipal authorities of Paris have for some time been operating their system of "holiday colonies" for needy children, the results of which are beginning to be studied. The boys gained on an average three and a half pounds in weight and the girls four, and they continued to grow in weight for nearly a month after their return to the city at a still greater rate. The boys gained on an average three-quarters of an inch in chest-girth.

In the *British Medical Journal* of January 21st, appears a news item, with the caption "Protection

in the States," which recites that not long ago, by virtue of a law forbidding the importation of contract labor, a trained nurse who had been engaged in London to take charge of the nursery department of the Pennsylvania General Hospital, was forbidden to land in New York, and was sent back by the next steamer on the ground that the engagement was contrary to the law. The same fate is probably in store for Dr. Heneage Gibbes, late of Westminster Hospital, who accepted an engagement as Professor of Physiology at the University of Michigan. The item infers that an effort will be made by disappointed candidates and possible rivals of Dr. Gibbes to have the law made applicable to him if he should venture to land in this country for the purpose of accepting his professorship. The article closes by saying that a more absurd kind of legislation it would be difficult to imagine. The absurdity consists in the supposition that it was the intent of the law to reach any persons of the station and profession to which Dr. Gibbes belongs; and, as was announced in our last issue, Professor Gibbes has already reached Michigan and begun his instruction in the University of that State.

REVIEWS.

Handbook on Diseases of the Skin, with Especial Reference to Diagnosis and Treatment. By Robert Liveing, A.M., M.D. Cantab., Physician to the Department for Diseases of the Skin at the Middlesex Hospital, etc. Fifth edition, revised and enlarged. 12mo. pp. 451. London and New York: Longmans, Green, & Co., 1887.

The author states that in this, the fifth edition of his handbook, many articles have been rewritten, and new ones have been introduced for the first time on erythema serpens, spurious erysipelas, malignant pustule, mycosis fungoides, colloid disease of the skin, rhinoscleroma, xeroderma maligna, scrofuloderma, Paget's disease, ulcers, leucoplakia, and lymphangioma. The reader will find, moreover, a suggestive chapter on nomenclature, together with remarks on classification.

After a careful perusal of the book we can recommend it as one of the most reliable works of its kind on the subject. It is by no means a compilation. It shows considerable originality, and is evidently the work of one who has seen a good deal of dermatology. The teaching on the whole is sound. There are some points, however, to which we must take exception, several of which may be briefly stated. Thus on page 29 the author states that he knows of "no one definite skin disease that can well be called ecthyma." In this country, especially in our large city hospitals and almhouses, a distinct idiopathic disease entitled to the term ecthyma is not infrequently met with. The existence of impetigo simplex is in like manner questioned. Dermatitis exfoliativa is made synonymous with pityriasis rubra, which we think a mistake, for there exist unquestionably two diseases with clinical features quite different, and the two names are therefore useful.

We are pleased to note that the author comes out boldly in favor of the non-contagious (non-parasitic) theory of alopecia areata. He says: "I have witnessed no case in which any proof was shown that the disease was caught from another affected person." In conclusion we are compelled to say that the weakest part of the book is the treatment, which rarely receives sufficient attention, and in the consideration of some diseases is positively wanting. Thus, taking up several diseases at random we find but three lines devoted to keloid; but two lines to alopecia areata; while comedo (sometimes a difficult affection to treat successfully) and purpura are both dismissed without any allusion to treatment.

The book will prove, we think, more valuable to the practitioner than to the student, and among other reasons because it possesses considerably more of the author's own experience than is usually met with in similar works.

SOCIETY PROCEEDINGS.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, February 2, 1888.

The President, Thomas M. Drysdale, M.D., in the Chair.

Dr. William Goodell reported a

CASE OF SPLENECTOMY.

Mrs. R., aged forty years, had chills and fever in early life, but after her marriage, eighteen years ago, she removed to a healthy country town and had no return of the disease. She has had two children, the youngest seven years ago. At this labor she had a serious flooding and was confined to her bed for six months from excessive prostration. Since that time she has never been well, being weak and miserable. Her monthly periods were always free and generally painful. Last March she had a very severe attack of what her physicians called malarial fever, and her life was threatened by repeated attacks of hæmatemesis and hæmoptysis. A tumor was now discovered which was pronounced to be a uterine fibroid and she was sent to Dr. Goodell. He found the womb pushed low down and retroverted by a solid tumor, which started from the region of the right ovary and ran diagonally toward the splenic region. It entered the pelvis so low down as to cause bulging of the anterior wall of the vagina. The womb seemed to be independent of the tumor, for the former could be moved about freely with the sound, yet when the tumor was pushed upward it conveyed motion to the womb, drawing it also upward. The tumor was never free from pain and the complexion of the woman was markedly cachectic. The diagnosis was made of sarcoma either of the right ovary or of the omentum.

At the operation a very long incision was needed, reaching not quite up to the ensiform cartilage. The tumor was of a dark purple color and was attached in every direction by very long, tortuous, and wholly denuded vessels, which looked like the largest earth worms and were of analogous length. Most of the vessels came from the omentum, which had disappeared,

apparently by being incorporated with the the tumor and by having its connective tissue and fat removed by absorption, leaving the bloodvessels bare. These vessels were either single or else grouped in large bundles and had all to be ligated. By them the tumor had evidently been nourished, for what looked like a pedicle was slender, long, and twisted. It was lost in such a mass of livid veins that Dr. Goodell did not dare follow it up to its source. His diagnosis had been sarcoma of the omentum, but he was so uncertain of it that he sent the specimen to Dr. Formad, who pronounced it a leukæmic spleen. It weighed not quite six pounds. The woman did well for four days, then symptoms of embolism set in, the sputa became streaked with blood, and she died on the sixth day. So far as he can learn from the literature on the subject his case made the eighteenth in which a leukæmic spleen had been extirpated and all had died save one.

Dr. Harris said that the case of recovery after operation for removal of a leukæmic spleen spoken of by Dr. Goodell had occurred under Dr. Franzolini, of Nudine, in Northeastern Italy. The proportion of leucocytes was small, which accounted for the recovery of the patient. The diagnosis had been made before the operation.

Dr. Parish had a few years ago seen a case with the late Dr. Wallace in which a diagnosis of fibroid of the uterus had been made. A tumor the size of the two fists was found near the side of the uterus. The patient developed peritonitis and was tapped; some dark fluid was withdrawn. Death took place a few months after, the peritonitis having been cured. The spleen was adherent to the uterus and to the pelvic brim.

Dr. Goodell called attention to the hæmoptysis and hæmatemesis in his case, which were the usual symptoms of a leukæmic spleen; but he had not been informed of them until after the operation had been performed, and, therefore, he did not have that clew toward forming a diagnosis.

DERMOID CYSTS.

Dr. Goodell also exhibited two dermoid cysts which he had on that day removed from a girl aged sixteen years. He had brought the specimens down because the largest one contained daughter-cysts or, at least, round bodies resembling them; yet he had hitherto found that all dermoid cysts which he had removed were single chambered and did not contain smaller cysts.

Dr. Hamill presented

A FOUR WEEKS' OVUM

entire with the decidua. He presented this specimen for a twofold reason; first, on account of its comparative rarity, and, second, to elicit from the members their views on the after-treatment of abortion. The decidua vera is not, as a rule, thrown off with the ovum entirely. Dührssen says, "From a personal experience with more than 150 cases of abortion in the service of the Charité of Berlin," that "the retention of portions of the decidua vera is not the exception, but the rule," and Tarnier says "That ordinarily the uterine decidua remains adherent to the uterus." Whether it is safer to leave this in the uterus and allow nature to throw it off, or to remove it at once, is the particular point he should like to hear the members discuss. For his own part, he felt sure that it should be immediately removed.

Dr. Hirst said that where the decidua vera is retained, as is the rule in early abortions, one of two things happened; the mass either putrefied and thus became a source of septic infection, or it became greatly thickened and remained as a foreign body exciting frequent hemorrhage or leucorrhœa. He always cleaned away any débris left in the uterus after abortion.

Dr. Goodell agreed fully with Dr. Hirst as to the propriety of removing the retained fragments of the placenta or the membranes, but he had a word to say about the manner of their removal. He deemed the much vaunted curette, whether sharp or blunt, a very inferior instrument, especially so whenever the fragments had been retained for several weeks. Not only did the curette bruise and injure the unimplicated portion of the womb, but it tended to glide over the fragment, merely scraping its surface. Sometimes, indeed, it would hook up one end of the fragment, and, after causing a great and needless flow of blood, would slip off. So often had he been disappointed with it, nay, even alarmed by the great loss of blood, that he now used either a small fenestrated polypus forceps, when the os was dilated enough to admit it, or a slender handled catch-forceps. With these instruments the fragment was invariably seized and removed by a twisting movement, while the womb itself sustained no injury whatever. It was, in fact, safer to use these instruments in the womb than to catch a stone in the bladder with the lithotrite.

Dr. Parish had seen a number of mistakes made with the curette. He had been called to a case and found a woman who had been bleeding for four or five months. Her former attendant had curetted her and pronounced the womb empty. He and his colleague dilated the cervix and removed a body as large as his two fingers. In another case the uterus was curetted by the attending physician and pronounced empty. Within twenty-four hours the patient aborted. These cases well illustrate how one may be deceived as to when the uterus is empty when relying on the curette. In his own practice, after three months, if there is retention he introduces his finger and delivers everything. He thinks with Dr. Goodell that something more reliable than the curette must be used to enable one to say that the uterus is empty after abortions in doubtful cases.

Dr. Longaker does not interfere before the third month at all unless the patient has decided signs of retention—such as hemorrhage, patulous os, etc.; otherwise it is, as a rule, safe to conclude that everything has come away. During the third, fourth, and fifth months retention is very frequent. He thought it surprising what a small portion of placenta would give serious trouble: even small shreds will keep up a very serious hemorrhage. He always removes everything which has been retained and uses the finger and very frequently anæsthetizes the patient.

Dr. R. Stewart asked the members of the Society in what proportion of cases they had to interfere. He has never used the curette for this purpose, and has never failed to remove with forceps of proper size. The hemorrhage generally ceases in from twelve to thirteen hours; if not he investigates and usually finds some débris left behind; but is convinced that, if there has been no improper interference at the time of the abortion, such cases are exceedingly rare. He agrees with Dr. Longaker as to the amount of trouble kept up by small pieces of membrane, etc.

DR. HAMILL also presented

A FŒTUS SHOWING INTRA-UTERINE RACHITIS.

This specimen presents a number of anomalies; probably the one most rare is the condition of intra-uterine rachitis; you will note the marked rachitic condition of both femurs. So far as he was able to find, but fifty-three cases have been collected by Schorlan and Gräfe. This condition of the bones in rachitis may be simulated by the arrest of bony development in those cases of fœtal cretinism occasionally met with in Europe. The absence of the three fingers and corresponding metacarpal bones would, following the classification of Geoffrey St. Hillaire, place this among the hemeteratic class, and the subdivision of that class known as anomalies by numerical diminution. This form of monstrosity is not met with very frequently. The absence of the fibulas renders the specimen still the more rare.

EXCISION OF THE LARGE INTESTINE.

DR. J. PRICE exhibited a piece of the large intestine which had been removed that day by Dr. Charles B. Penrose. The patient, a woman, had not had a passage of the bowels for twenty-eight days. There was enormous distention. The constriction was easily found on the right side of the uterus and posterior. The intestine was punctured and a gallon or more of feces removed. The gut was then resected, a piece twelve inches long being removed. The two ends of the gut were then united in half their circumference and the other half stitched to the abdominal opening, making an artificial anus. Dr. Agnew had seen the case and had recommended immediate operation. The woman was a patient of Dr. Bernardy's. She is now doing well. He believed that Mr. Tait had first advised the preliminary puncture to relieve the distention in conditions that cannot be dealt with by resection. He had some letters from Dr. McMurtry, of Danville, Ky., who had been called forty-five miles into the country to see a physician twenty-six years old. On opening the abdomen he found two perforating ulcers of the cæcum with local peritonitis. He had trimmed the edges of the ulcers and closed with Lembert sutures; irrigation and drainage. On the fourth day, pulse 92, temperature 99°, and patient had complete evacuation of bowels.

THE MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, February 3, 1888.

THE PRESIDENT, JAMES PERRIGO, M.D., IN THE CHAIR.

DR. STEWART showed a case of

AMYOTROPHIC LATERAL SCLEROSIS,

and made the following remarks:

The patient, a man aged thirty-four, always enjoyed good health until his present affection began, about a year ago. The first symptom complained of was a feeling of pricking coupled with a cold sensation on the ball of the left thumb. Shortly afterward wasting of the thenar eminences was noticed, and this was quickly followed by wasting of the interossei of the same hand. The patient now has very marked atrophy of the left thenar and hypothenar eminences, of all the interossei of the same side, with slight wasting of the flexors on the anterior surface of the forearm and of the biceps and deltoid of the same side. The spinati as well as the rhomboids and pectorals are the seat of marked atrophy. There is slight wasting of the corresponding muscles of the right hand, arm, and shoulder. The atrophic muscles are subject to fibrillary twitchings. Many apparently normal muscles are also subject to these twitchings; he complains of "waves of twitchings" passing through the muscles of the head. The muscles of the lower extremities are very frequently the seat of these troublesome twitchings. The left hand and shoulder atrophic muscles exhibit a modified reaction of degeneration, the contractions being very slow, while the ASZ < KSZ. During the past ten days there has been a gradually increasing loss of power in the left lower limb. This has now attained a degree almost sufficient to prevent the patient from going about. The degree of paralysis varies considerably from day to day. The paralyzed muscles are neither atrophied nor hypertrophied; they are, however, in a constantly hypertrophic state. There is marked exaggeration of the knee-jerk, ankle clonus is present. The biceps and triceps reflexes of the upper extremities are marked also. The integument over the wasted districts is constantly covered with a profuse, clammy perspiration, and at times a papular rash appears lasting only a few hours. There is no atrophy of any of the face muscles, and no history of heredity. The case is evidently myelopathic in origin. It is a well-marked example of Charcot's amyotrophic lateral sclerosis.

DR. SHEPHERD presented the right half of the lower jaw which he had recently removed for

PERIOSTEAL SARCOMA.

Patient, aged forty-nine, first noticed swelling six months ago, this was accompanied by the loosening of two molars. Swelling increased rapidly within the past three weeks. The tumor surrounded the jaw at its angle and was about the size of an orange, the bone was not affected. On microscopic examination it proved to be a round-celled sarcoma. Dr. Shepherd said in these cases the chance of local recurrence was very great.

DR. JOHNSTON exhibited for Dr. Ruddick a spinal column showing very extensive

CARIES OF THE VERTEBRÆ

with symmetrical psoas abscesses. The specimen was removed from a boy aged twenty. The caries involved the bodies of all the dorsal vertebræ. In front of the middle dorsal vertebra was a large abscess which had formed without giving rise to symptoms, this abscess was not connected with the psoas abscess. The bodies of the last dorsal and first and second lumbar vertebræ were completely destroyed, causing a marked angular curvature. The psoas abscesses were perfectly symmetrical, passing in front of the ilio-psoas muscle at Poupart's ligament, and following the tendon to the posterior part of the lesser trochanter, thus the abscesses had got to the back of the thighs. On the left side the abscess had reached the popliteal space. That on the right side presented a large fluctuating swelling in the middle of the back of the thigh and had filled up the space beneath the gluteal muscles. The abscess on the left side had been opened a few days before death and an enormous quan-

tity of pus evacuated. The lad had suffered from spinal caries for the last fifteen years, and had never had any treatment. Dr. Johnston failed to find any tubercle bacilli, either in the pus or in the walls of the abscess.

Dr. Johnston also presented a portion of the spinal column removed from a patient with

SPINAL CARIES AND GENERAL TUBERCULOSIS.

The bodies of the second and third lumbar vertebræ were infiltrated with extensive caseous areas, a small tuberculous abscess had formed on the right side at the level of the third lumbar body; this had involved a small vein opening into the vena cava inferior. There was acute miliary tuberculosis of both lungs, and this had caused his death. The patient had been under the care of Dr. George Ross, and had complained of very severe and deep-seated pain referred to the right sacro-iliac articulation.

Dr. Shepherd presented the kidneys and bladder removed from a patient on whom he had performed

NEPHROTOMY.

The history of the case is as follows: C. W., æt. sixty-six, a tall, thin man, who had always been healthy, though there was a tuberculous family history, some two years ago suffered from two attacks of well-marked renal colic affecting the left side. After this he made water more frequently, and occasionally passed bloody urine. He, however, attended to his business as usual. About a year ago he first noticed that his water was thickish; it would be clear for some days, then have quite an amount of deposit. His health failed considerably during the last six months, and in October last he took to his bed on account of a chill. The amount of "sediment" in the urine increased and micturition became painful as well as frequent; pain was referred to the point of the penis. In addition to this he had severe lumbar pain, chiefly on the right side.

Dr. Shepherd first saw him in the latter end of December, 1887. He was then in bed and suffering from disordered stomach, frequent and painful micturition, and severe lumbar pain. Examination of the bladder discovered a moderately enlarged prostate, but no stone. Urine, specific gravity 1010; alkaline; quantity daily, forty-five to fifty ounces, of which about one-sixth was thick pus. The urine was perfectly sweet smelling. On examining the lumbar region there was found to be much more resistance over the right kidney than the left and palpation gave a sense of fulness. Pressure below the last rib on the right side caused severe and sharp pain, pressure on the left side caused no pain. Dr. George Ross saw the patient with Dr. Shepherd and he was examined under ether and a distinct tumor was made out in the right lumbar region in the neighborhood of the kidney. By aspiration at this point some four or five ounces of clear fluid were drawn off, but no pus. This fluid was odorless, but on examination proved to be urine. After examination the patient passed bloody urine for two days. The diagnosis made was calculous pyelitis probably of the right kidney, but the history of renal colic on the left side and the evacuation of clear fluid from the right kidney made the diagnosis doubtful.

As the patient was growing rapidly weaker and was passing enormous quantities of pus, it was suggested that an operation might relieve the patient, though the result would be doubtful. On January 21st Dr. Shepherd, assisted by Dr. Fenwick, cut down on the right kidney. It was found embedded in a large amount of fat. On examination it was seen that the pelvis and calices were much distended; the kidney was incised and some six ounces of fluid evacuated; there was no pus but only clear, odorless fluid. The kidney was explored, but no pockets of pus discovered and no stone, the wound was sutured and a large drainage tube introduced. The patient recovered well from the operation, but secreted no more urine, rapidly became uræmic, and died two days later. Of course, when the condition of the incised kidney was seen it was supposed that the wrong kidney had been cut down on; however, a post-mortem examination revealed a similar condition of the left kidney.

Dr. Johnston made the post-mortem examination and his report is as follows:

"Autopsy, twelve hours after death. A very strong urinous ammoniacal odor noticed about the body, which was well nourished. Abdomen only examined. The kidneys did not project below the level of the last rib. Both ureters distended to almost the size of forefinger. The kidneys on both sides showed marked hydronephrosis with dilated pelves and calices, papillæ flattened. Renal substance atrophied and microscopically showed extensive cirrhotic changes, but was free from any appearance of true inflammation. The pelves and ureters contained opaque purulent looking fluid, but the mucosa nowhere eroded. Bladder contained about ten ounces of dark urine and pus was sacculated behind prostate and the middle lobe was enlarged but soft. Muscular coat of bladder much thickened and trabeculæ prominent, the mucosa, on the contrary, was very thin and atrophied and showed deep-seated pigmentation."

Dr. Johnston, in commenting on this case, said the most interesting symptom was the presence of what appeared to be pus in the urine—that is, a dense cellular deposit not accompanied by much mucus. This had always been given as a sign by which suppuration of the kidney could be distinguished from catarrh of the bladder and in this case had materially influenced the diagnosis. Here, however, there was no true pus present in the sense of a product of suppuration accompanied by necrosis. The anomaly was probably explained by the condition of the bladder mucosa which showed a marked atrophy; in most cases of cystitis following prostatic obstruction the bladder mucosa is greatly thickened. This atrophic mucous membrane being unable to secrete any considerable amount of mucin had made the appearance of the urinary deposit very misleading. The absence of mucus was the reason why the urine was not foul.

Dr. Shepherd said he had now no doubt that the case was originally one of enlarged middle lobe of the prostate followed by secondary changes in the ureters and kidneys the result of obstruction. Still, he thought the case a very obscure one and one in which the diagnosis of calculous pyelitis was justifiable both from the history and symptoms. Dr. Johnston had explained the reason of the absence of mucus and the cause of the urine remaining sweet, but the deposit was so large in amount that it must have proceeded from the whole urinary tract and not from the bladder only.

Dr. Kennedy read a paper on a case of

DIABETES

in which a daily analysis of the urine had been made from October, 1886, to August, 1887. The patient was a female, aged twenty-eight years. Tables were shown recording the daily quantity of urine, the specific gravity, amount of sugar, urea, and amount of fluid and food taken. At the commencement of the treatment the average daily amount of sugar was seven ounces. Codeia was first given with benefit, but lost its effect during the second week, when the patient's condition became serious. On December 10, 1886, nitro-glycerine was given and continued with slight intermissions for five months; its action was markedly beneficial, for the patient's condition steadily improved.

So far as Dr. Kennedy was aware, this was the first time the remedy had been used in diabetes. Jambol was given for a short time as an additional remedy, but not continued. Iron, strychnine, etc., were also given for the anæmia. A strict diabetic diet was followed with saccharine as a sweetening agent. In July, 1887, no medicine was given as the patient was almost well and during the last week of the present month (January, 1888) the patient's condition was normal and there was no sugar in the urine. At the present time the patient is perfectly well. During the ten months the urine was examined the patient excreted fifty-two pounds of sugar.

Dr. Ruttan said that this case deserved more than a passing notice. There was probably not another case on record in which such an accurate and thorough analysis of the urine had been made. A daily quantitative estimate of the most important constituents of a diabetic patient's urine, extending over a period of ten months, should reveal something of interest. It was important to note the fact that whenever there was a sudden decrease in the percentage of sugar there was an increase in the acetone group of excreta and this was accompanied by the most alarming symptoms. Whether there was any relation between the quantity of sugar and acetyl-acetic acid excreted has not been determined, but there are few who believe that the symptoms of diabetes are due to the sugar or want of proper assimilation of carbohydrates. If these acetone products do not of themselves produce the toxic symptoms and coma of diabetes, their appearance during and preceding coma is a remarkably common coincidence. In a recent case of sudden diabetic coma Dr. Ruttan had examined the urine, found it a trifle pale and with no acetone odor when fresh. Sp. gr. 1020; only 2.7 per cent of sugar, but the acidity was equal to $\frac{27}{100}$ of a grain of oxalic acid per ounce, and it was loaded with acetyl-acetic acid. In another case recently examined by the speaker, for life insurance, no sugar reaction was obtained by Fehling's solution, but the acetone reaction was marked. Sp. gr. normal. Two days later this patient's urine gave 3 per cent. of sugar and no acetone. Sp. gr. 1028. The specific gravity of diabetic urine is no index to the quantity of sugar, nor, indeed, if acetone be found, is it in relation to the total solids, for the acetone and alcohol resulting from the decomposition of acetyl-acetic ether will greatly lower the specific gravity. Dr. Ruttan, in conclusion, stated that no work of much clinical interest could be done in connection with acetonæmia or diacetonæmia until a more convenient method of isolating acetone is found than that recommended by Salkowski.

Dr. T. Wesley Mills said that the elaborate daily analysis of the urine in Dr. Kennedy's case could not but prove of value. We have much to learn yet about diabetes. Why should irritation of the fourth ventricle produce sugar? He was not himself satisfied with the present condition of our knowledge of the medulla, and doubted much whether it has all the centres that are attributed to it. It seemed to him that when we do not know where to put a centre we place it in the medulla. He hoped Dr. Kennedy would publish the tables of his analysis of the urine in full.

NEWS ITEMS.

The Crown Prince.—The *British Medical Journal* of February 4th states that the slough which came away on January 17th, from the site of the growth which excited so much alarm in November, was more than three-quarters of an inch long. The raw surface left by the separation of this piece of disorganized tissue has now almost entirely healed, and the condition of the neighboring parts is highly satisfactory. There is, however, some thickening about the right side of the larynx; and though the present appearances seem almost to negative the theory that the disease is malignant, a dangerous amount of narrowing of the breath-way may be caused by simple inflammatory swelling. Under these circumstances it is thought not improbable by the physicians in charge of the case that tracheotomy may become necessary, possibly at no very distant date. This contingency, however, while requiring to be kept in view, need not cause any special anxiety as to the prolongation of the life of the illustrious patient.

As is well known, the tracheotomy, which was foreshadowed in the above article, has since been performed.

In reference to the pathological character of the slough from the site of the growth, the *Lancet* states, on the authority of the *Vorsiche Zeitung*, that Professor Virchow, after the most careful and minute investigation, is unable to discover in the portion submitted to him anything of a really serious character.

Sanitary School Reform.—The Commissioners of Public Schools of Baltimore, Md., have taken the initiative in the introduction into the public schools of that city of a series of reforms which, if adopted, will be of great benefit to the pupils. This action is the more noteworthy from having originated in the School Board, the proposition coming from its Committee on Health, and not being forced upon it by the Board of Health or public opinion. It is greatly to be hoped that the Mayor and Common Council of the city will give the necessary power and money to carry these resolutions into effect. After a preamble to the effect that sanitarians and teachers have proven that children attending school are frequently subjected to influences prejudicial to health, which often leave their effects upon the constitution for life, and that it has been demonstrated, that, by expert sanitary supervision of schoolhouses and of the pupils themselves, many of these injurious influences can be mitigated and removed, the resolutions are, that the Mayor and City Council be requested to authorize the Commissioners of Public Schools to appoint an officer, who shall be a physician and expert in sanitary science, to be known as the Sani-

tary Superintendent of Public Schools, whose duty shall be, 1st, to examine carefully all plans submitted for the construction of new schoolhouses, and suggest such modifications as may be necessary from a sanitary point of view; 2d, to advise with the Commissioners with reference to necessary alterations in school buildings to improve their hygienic condition; 3d, to examine all textbooks before adoption, in order that type, printing, or paper injurious to the eyesight of pupils may be avoided in selecting such books; 4th, to satisfy himself, by personal examination, if necessary, that all pupils admitted to the schools have been properly vaccinated or are otherwise protected against smallpox; 5th, to take such other measures, in conjunction with the Health Commissioners of the city, as may be necessary to prevent the spread of contagious diseases in, or through the medium of the public schools; 6th, to examine annually the eyesight of all children attending the public schools, and keep an accurate record of such examinations; 7th, to report annually, or as often as may be required by the Commissioners, upon the sanitary condition of the schools, and of the pupils attending them, and to advise the Commissioners upon sanitary questions connected with schools whenever required; 8th, to give instruction, by lectures or otherwise, to the teachers in the schools upon the elementary principles of school hygiene.—*Science*, February 3, 1888.

The Electric Light for Reading Rooms.—In the annual report for 1887 the "Stadtphysicus" of Prague, Dr. Zahor, urges the introduction of electric lighting into the public reading rooms. He states that Dr. Fr. Renk, assistant to Professor Pettenkofer, has had the opportunity of making a series of experiments on the utility of the electric light from the sanitary standpoint, in the "Nationaltheatre" of Munich, which is supplied with 1700 Edison lights. He has thus been able to prove that the electric light had hardly any influence on the deterioration of the air, whereas the gaslight raised the temperature of the room, deprived the air of its oxygen, and rendered it injurious by increasing the carbonic acid, especially in the higher regions. It could also be easily imagined that the elevation of temperature produced by the gaslight, the increase of the carbonic acid, and the diminution of the oxygen in the air reached a much higher degree in confined working rooms than in a spacious, well-ventilated theatre. Considering that when the electric light was used such an increase of the local temperature could never take place as when gaslight was employed, and that in the latter case headaches referred to those parts of the head which were directly exposed to the influence of the rays of light, neuralgias, and local hyperæmias supervened; furthermore, that no carbonic acid was developed, and that no oxygen was consumed by the electric light; and lastly, that, although the electric light was very powerful, its intensity could be diminished by shades—it became evident that the more general adoption of the electric light would be very advantageous from the hygienic point of view.—*British Medical Journal*, January 28, 1888.

A Series of Evening Lectures on special subjects will be given by the faculty of the Philadelphia Polyclinic at the college building, Broad and Lombard Streets. Dr. Leffmann will open the course on the 28th inst., subject: *Office Testing of Urine*. Members of the profession are invited to attend.

The Extermination of Rabbits.—The *British Medical Journal* writes that M. Pasteur's plan of exterminating rabbits by the spread of fowl cholera has been tried in a walled field near Rheims, where both gun and ferret had proved ineffectual. M. Loir, nephew of M. Pasteur, went down and poured on a truss of hay some broth full of the microbes of chicken cholera. The next day nineteen dead rabbits were found, and two days later twelve more. In some of the burrows were discovered families of dead rabbits, and not one living rabbit has since been seen.

A Polish Medical Congress will be held in May, 1888, at Lemberg.

New Teachers at Vienna.—The following *Docenten* have recently been appointed: Drs. Neusser (Medicine); Hochstetter (Anatomy); Kolisko and Paltauf (Pathological Anatomy); Ehrmann (Dermatology and Syphilis); v. Hacker (Surgery); Unger and Frühwald (Diseases of Children).

An Itinerant Dispensary.—An itinerant clinic or dispensary has been established in Roumania under the direction of Dr. Bejan, of Bucharest. During last summer, itinerations were made in two districts in which there is a great scarcity of doctors, and no less than 9000 patients were treated.

Professor Senator has been appointed Director of the Medical Department of the Berlin University Polyclinic.

Another New Anæsthetic.—The *Medical Press and Circular* of January 25, 1888, reports that Dr. Lewin, having been commissioned to examine a new arrow poison forwarded by Messrs. T. Christy & Co., reports that it is a powerfully toxic agent when injected subcutaneously, even in quantities of $\frac{1}{300}$th grain. It also possesses marked anæsthetic properties when applied to the cornea, but its use was followed by some irritation. A careful examination of the substance has enabled him to identify it with the *Haya* arrow poison, obtained from the *Erythrophlæum judiciale*, which, when pure, produces insensibility of the cornea without irritation.

A Generous Transfuser.—The *British Medical Journal* reports that on January 13th, Dr. Eustace, a young practitioner at Alresford, Hants, was summoned at midnight, and found his patient suffering from uterine hemorrhage. This he stopped, but in the morning the patient was almost pulseless and sinking fast. Dr. Eustace, with no one to help him but an old woman, opened a vein in his arm and tried direct transfusion, but lost a quantity of blood, so, allowing over six ounces of blood to drop into a basin, he injected it with a syringe, with the result that the patient after a week had recovered.

Electric Sunstroke.—The Paris correspondent of the *Medical Press and Circular* of January 18, 1888, writes that at a recent meeting of the Academy of Medicine M. Terrier read a paper on "electric sunstroke" observed in some workmen at the great foundry of the Creusot, who

smelt steel by electricity. The neck, face, and arms of the men became red and painful, and, finally, desquamation took place as witnessed in burns of the first degree. M. Terrier said that he exposed his arm during a few minutes to the action of the incandescent electric light and at the end of an hour the arm assumed an intense redness, which, at the end of four days, gave place to the ordinary desquamation. As to the cause of these symptoms he considered it difficult to determine, as heat could not produce them since electricity emits hardly any caloric.

Women Pharmacists in Italy.—There is a dearth of pharmacists in the rural districts of Italy. The Minister of the Interior recommends that women be given opportunity to study and practise pharmacy, although he would not go so far as to allow them to receive the degree of pharmaceutical chemist. That will come, however, in due time.—*Exchange.*

French Toilet Articles. — The *American Druggist* for January, 1888, writes that in a report submitted to the Hygienic Council of Paris by Drs. Dubrisay and Chafin, the authors state that the perfumery and toilet products now sold contain so many noxious substances that it is desirable the factories should be placed under special surveillance. They give a number of instances in support of their statement. The so-called "harmless and purely vegetable" hair dyes, they say, are all poisonous. "Progressive dyes" are ammoniacal solutions of nitrate of silver. The "instantaneous dyes" are a solution of litharge in lime water. "Eau des Fées" is a solution of sulphate of lead in hyposulphite of soda. "Eau Figaro" consists of three solutions (1) of nitrate of silver and sulphate of copper; (2) sulphide of sodium; (3) cyanide of potassium (to remove the silver stains). "Eau des Fleurs" is composed of rose water, 95.5; flowers of sulphur 2.7; acetate of lead, 2.8. Passing to cosmetics, they say "Lait antipellique" is composed of corrosive sublimate, 1.7; oxide of lead, 4.22; sulphuric acid and camphor. "Lait de manille" is a mixture of borax, copper, tincture of benzoin, and essence of bitter almonds; "Lait de Ninon," of bismuth and zinc; "Eau Magique," oxide of lead and hyposulphite of zinc; "Eau de fleur de lys," protochloride of mercury; "Eau royal de Windsor," glycerin and oxide of lead; "Eau de Castille," hyposulphite of soda and acetate of lead. The "Poudre Pilivore de Laforet" contains mercury (?), 60 grs.; sulphide of arsenic, 30 grs.; litharge, 30 grs., and starch, 30 grs. "Epiteine" is simply sulphite of calcium, and "Antiboldos" hyposulphite of soda. Pomades against baldness all contain cantharides and croton oil.

Permanganate of Potassium in Toothache.—In the *Russkaia Meditzina*, No. 19, 1887, p. 330, Dr. Prokopy Popoff, of Minüsinsk, in "Siberian Switzerland," writes that he has most successfully treated upward of three hundred cases of toothache from dental caries by administering one-twentieth per cent. solution of permanganate of potassium in the form of a mouth wash. The following is the formula: R.—Potass. permang., 3 grains; aq. destil. or fontanæ, 1 (Russ.) fl. pound.—Misc. One tablespoonful to be taken in the mouth, every half hour, and to be held therein on the affected side for several minutes. The most agonizing pain is said gradually to disappear in a few hours. The wash acts, besides, as an excellent deodorizer.—*British Medical Journal*, January 7, 1888.

A Terrible Suicide.—The *British Medical Journal* reports that in the case of Rear-Admiral Verstrume, who died by his own hand at Falmouth, the deceased was found to have thrust a red-hot poker three or four times into his abdomen.

A Hygienic Kitchen.—In an article in the *Popular Science News* for January, 1888, Dr. Crowell describes a healthful kitchen as follows:

The kitchen should receive special attention, for it is here where the important work of the household is done. And yet how often is this apartment neglected in the plan of the house, and crowded away in some angle, small, dark, and inconvenient. A kitchen should be at least fourteen feet square, with ample arrangements for range, sink, and other culinary appliances. The sink should be thoroughly trapped, the water that supplies the tank should *not* come from the cistern that feeds the water-closets, and the drip-pipe of the refrigerator should not enter the general sewer. The backs of sinks and wash-tubs should be protected with high soapstone slabs, to prevent the accumulation of moisture and filth; and care should be taken that no waste material finds lodgement in any of the crevices or traps. Open plumbing should be observed, and no place should be found under sinks for mops or rubbish. The floor should be solid and seamless, with grooved edges where it joins the mopboard. This concave line prevents the accumulation of dust and vermin, and greatly facilitates the process of cleaning the floor.

To Cool Water Without Ice.—Where ice cannot be procured, water may be cooled by wrapping the pitcher containing it in a towel of loose texture which has been previously impregnated with ammonium nitrate (*and dried*) and moistening this with water. The same towel may be used repeatedly, being dried thoroughly beforehand each time.—*Pharmaceutical Era.*

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM FEBRUARY 7 TO FEBRUARY 13, 1888.

JANEWAY, JOHN H., *Major and Surgeon.*—Detailed as a member of the Army Retiring Board in San Francisco, Cal., covered by S. O. 168, A. G. O., July 22, 1886.—*S. O. 28, A. G. O.*, February 4, 1888.

HOPKINS, WILLIAM E., *Captain and Assistant Surgeon.*—Detailed as a member of the Army Retiring Board in San Francisco, Cal., covered by S. O. 168, A. G. O., July 22, 1886.—*S. O. 28, A. G. O.*, February 4, 1888.

JARVIS, NATHAN S., *First Lieutenant and Assistant Surgeon.*—Ordered from Fort Lewis, Colorado, to Fort Leavensworth, Kansas.—*S. O. 30, A. G. O.*, February 7, 1888.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

EXTRACTION OF CATARACT WITHOUT AN IRIDECTOMY.

A Clinical Lecture delivered at the Garfield Hospital, before the Post-graduate School of Ophthalmology.

BY SWAN M. BURNETT, M.D.,

PROFESSOR OF OPHTHALMOLOGY AND OTOLOGY IN THE UNIVERSITY OF GEORGETOWN; OPHTHALMIC AND AURAL SURGEON TO THE GARFIELD HOSPITAL, AND DIRECTOR OF THE EYE AND EAR CLINIC AT THE CENTRAL DISPENSARY, WASHINGTON, D. C.

GENTLEMEN: That wise man and emperor, Marcus Aurelius, found out, nearly nineteen hundred years ago, that the "World is only change and life only opinion." The experience of the succeeding centuries has in no way invalidated the truth of this observation, whether as applied to life in general or to things in particular. Change is the order of to-day, as it always has been, and always will be until a stable equilibrium is reached between man and his environment. Certainly, in the art of medicine, this is too apparently true to need any argument for its substantiation. The only point then that should interest us, as practitioners of this art, is whether proposed changes are in the direction of progress or retrogression. Certainly, all change is not progress, and yet it cannot be doubted that most changes in medicine are associated with a loss of some error, or the further elucidation of some hitherto obscure truth.

Ophthalmic surgery, like all other arts, and particularly the arts based on scientific knowledge, has had its periods of activity and repose. Anything like a complete survey of these changes is, however, beyond the range of the purpose of this lecture, the object of our particular interest at this time being the present status of the operation for the extraction of cataract. From the time of Daviel's grand achievement to the present, there has been only one marked innovation in the methods of extracting cataracts. Up to v. Gräfe's time extractions were made, whether by instruments or otherwise, through a corneal incision made by a triangular-shaped knife. Occasionally a bold spirit would make some slight deviation from the established procedure, but the encouragement he received was scant, and at the period when the genius of v. Gräfe was thrown on the world, the "flap" extraction through an intact pupil had become classical. When we consider the tremendous superiority of the results obtained by this method over those following reclination, it is no wonder that there was an indisposition to change, and a general feeling of content with "well enough."

All the factors leading to this marked change in the method of extraction may not be altogether clear now, but that it followed in the train of the prevailing opinions of the period, is quite certain. No innovation so radical as this ever comes about suddenly. It may come as a climax, but its antecedent accumulating causes are usually not far to seek. The association of iridectomy with cataract extraction, was most probably the outcome of v. Gräfe's experience in the therapeutic value of excision of a piece of the iris in glaucoma and other morbid conditions of the eye. He adopted it as a part of his method in order to forestall certain complications and ill results which had hitherto lain in the way of the best results. At that time iridectomy had achieved such marvellous success in glaucoma, and its application was pushed into so many and such diverse fields of therapeutics, that there was danger of oculists becoming simply iridectomists. One eminent London surgeon, it was said, thought it a dull day when he made less than half a dozen iridectomies in his private practice alone.

But a truly great mind like v. Gräfe's would not be led away by a mere fashion, and particularly by one which he had himself instituted. He had, undoubtedly, the prophylactic power of iridectomy in view when he adopted it as a part of his method, but there were other reasons inherent in the method itself which rendered it apparently necessary. The extreme peripheral position of the incision, which he adopted for the purpose of making it as nearly linear as possible, and to lessen the chances of corneal suppuration which was the cause of the loss of so many eyes in the old flap method, made a prolapse of the iris almost a matter of course. This, and the evil consequences which would almost surely follow, could be avoided only by making an excision of the iris, corresponding in extent, or nearly so, with the corneal incision.

The extremely satisfactory results of this "peripheric linear method" as v. Gräfe called it, together with the great weight of authority of its originator, established it as firmly among operators as the old flap method had been, and within a very few years after the method became known, the operation without an iridectomy was done only by one or two very conservative surgeons, always to be found, who believe that old ways are best. But, in spite of all this, the world of ophthalmology still continued to move—almost imperceptibly, it is true, but yet sufficiently for a careful observer to note, that after a certain number of years the "Gräfe" operation was not exactly the same to all men, and, in fact, in course of time the typical "Gräfe" was done by but a limited number of his disciples. First of all, the section was shifted a little more forward, and ceased to be strictly peripheral. This was done because some cases of sympathetic ophthalmitis were reported, which seemed to depend upon the injury to the ciliary region in the operated eye. And then again, prolapse of vitreous was much easier with a wound almost wholly scleral. The incision being then brought wholly, or almost so, in the cornea, ceased to be "linear," and thus the name the author had given to it could no longer be considered as accurately descriptive. But still the iridectomy remained, and for many years that and the narrow knife were all that could be truth-

fully said to remain of the "Gräfe" method of extraction.

It is not to be supposed, however, that the whole ophthalmological world bowed the knee to v. Gräfe and accepted the operation as it left his hands. One of his own pupils—Liebreich—devised a downward section situated wholly in the cornea, and extracted without an iridectomy; and the "Brussels" operation was very similar, the incision being made upward and curvilinear in form. The late Mr. Critchett, of London, was in the habit of doing the "Brussels" quite frequently when I was at Moorfields, twelve years ago. There are some others who made tentative efforts in the same general direction, but it was de Wecker, of Paris, who with his characteristic energy and enthusiasm, first tried the new method on an extensive scale. I think there is a diposition in certain quarters to give to others the credit which is really due to de Wecker as the pioneer in the operation which is now coming rapidly to the fore. I remember when I was following his clinic in 1875 and '76 he was doing essentially the same operation as is now being done, and was striving earnestly to impress its value on the profession. Speaking to me one day about it, he said, "They take to my iritomy, but"—with a sad shake of the head—"they will not accept my method of cataract extraction."

It must be a source of considerable satisfaction to him to know that the profession has, at last, accepted it, at least for trial, and that many of our best operators now say they will never make an iridectomy again, except in particular cases. He himself does not do it in all cases, but for the common, uncomplicated senile cataract his "extraction simple" is the operation which in the near future will undoubtedly be the rule, and will remain so until something better is devised. Of course, the ideal extraction is with the lens in its capsule and without an iridectomy, and we shall not despair of its final realization, but, for the present, we must content ourselves with progress in that direction.

It is an interesting and instructive inquiry as to the causes that have led to a final adoption of this "simple extraction." As I stated before, one of the principal reasons which led v. Gräfe to make the iridectomy was the danger of prolapse of the iris, and with the extreme peripheral section he employed, this was unavoidable. But when the section was moved farther forward, it was found that the iris could, by a little coaxing, be made to return, after the lens had been pressed through the pupil, and frequently with no tendency to prolapse. The introduction of eserine, the active principle of the calabar bean, also assisted, in so far as the contraction of the pupil which it causes, renders a prolapse more difficult—at least it is supposed so by many, and the first operations without an iridectomy were all accompanied by instillations of a solution of eserine. It was also found that the incision at the corneal margin was not more likely to be followed by suppuration than when it was scleral, while the dangers of cyclitis and of sympathetic ophthalmia were materially lessened. It is true, prolapse of the iris would take place sometimes in spite of the best precautions and the greatest care, and posterior synechiæ were by no means infrequent, but yet the majority of the patients recovered with round pupils, and in many instances with movable ones. Still, as we have said, the innovation made no great headway; the conservatives were satisfied with things as they were, and a large coloboma of the iris was not to them a matter of much consequence, so long as their patients saw well.

I, am, gentlemen, not an advocate or defender of rashness or unwarrantable boldness, but I think the self-styled conservative is, usually, the man who waits for somebody else to tell him what to do and the best way of doing it. These conservatives are afraid of iritis and synechia, forgetful that in only a very limited number of cases did the iridectomy prevent the occurrence of iritis in some degree, and ignoring the fact that in nearly every case the stump of the excised iris was entangled in the corneal wound even when the pupillary edge remained free, which it did not always do, by any means.

There was no great overpowering name, like that of v. Gräfe, to bolster it up, and the fact that the operation without iridectomy was revived in France would not materially hasten its adoption in Germany,[1] and in these days the stamp of German authority is quite necessary for matters ophthalmological. But de Wecker's persistency finally had an effect, and gradually the "extraction simple" began to be tried in selected cases by first one and then another, until now it is the question when one oculist meets another, "Are you doing extraction without an iridectomy, and how do you like it?" And the reply almost universally is, "Yes, I have done it in a few cases and I rather like it, and shall try it in more." When in New York this winter I found all the prominent men doing it, and, on the whole, they were very well satisfied with the results, and I have no doubt we shall hear from them, in print, to that effect soon.

The question also came up for discussion at the late International Congress, held in Washington last September, and there was a free interchange of opinion as to its merits. Of the Frenchmen present, all but Landolt did the operation as a rule. Mooren, of course, advocated his own plan of a preliminary iridectomy, while Mr. Henry Power, of London, said that he thought he should never, except in extraordinary cases, do an iridectomy again.

My own judgment in the matter is that in the good cases the results are better, and in the bad cases they are no worse than when an iridectomy is performed. Prolapse of the iris is, in my opinion, not any worse than the incarceration of the stump of the excised iris in the wound. Iritis is not any more frequent, according to my experience, than when an iridectomy is made.

As to visual acuteness, we have not had a sufficient number of cases to compare results, but, on general principles, it must be conceded that a round central movable pupil is optically better than a large coloboma. Neither should the question of appearance be ignored. Our patients have the right to expect of us the best results with the least possible amount of disfigurement; and one of the reasons de Wecker is said to have given for cultivating this method is that his clientele was so keenly sensitive to the æsthetic features of the question that he felt that he must get rid of the regulation mutilation of the iris.

But, after all, I think it may be said that one of the most

[1] It is only just to say that this statement is not applicable to all Germans. Prof. Schweigger, of Berlin—v. Gräfe's successor—does the operation, and is a strong advocate of it in proper cases, and his influence will undoubtedly be great in establishing it in Germany.

powerful promotors of the operation was the introduction of cocaine as a local anæsthetic. It is well known that the application of the cocaine solution to the outside of the eyeball acts but feebly on the iris, even when the solution is a strong one and is applied for some length of time; and even when the solution is applied directly to the iris there is not always a sufficient anæsthesia to make its section absolutely painless, though some contend that they have uniformly succeeded. Without an iridectomy the operation under cocaine is perfectly painless, and we can so assure our timid patients, and this assurance as to its being nearly painless allows them to submit more readily to an operation, renders them quieter under its performance, and, undoubtedly, by this quietude of mind conduces to a better final result.

It is not claimed that it is a method that is adapted to all cases. There are certain cases in which an iridectomy is to be preferred as being safer. I do not consider, however, that a large nucleus is a contraindication. I have extracted a brown cataract which was nearly all nucleus through an intact pupil with excellent results, and one Morgagnian cataract in which the small nucleus was floating in a liquefied corticalis, turned out most beautifully. So far I have found but three classes of cases in which I have considered it unsafe to dispense with an iridectomy, and these are the instances where there is a great deal of soft corticalis, or the cataract is immature and where the pupil is rigid, or where there is a tendency to glaucoma. There are some operators, however, I believe who do not make an exception even in such cases as these.

As to the *technique* of the operation, it is essentially the same for all operators who are at present doing it, though there are special features of detail peculiar to some. As a rule, the narrow Gräfe knife is used, though some prefer a modification of the old triangular Beer's knife. Most of you have seen me do the operation a number of times in this hospital, but it may be well to go over again connectedly the various steps of the method as at present followed by us.

As you see, all our operations are done in the open wards of the general hospital. We have no dark rooms or dungeons, but plenty of light and air, and whatever cheerfulness may come from the presence of others in the same room and moving about, which, in my opinion, is not inconsiderable. The patient is given a bath and put in the bed in which he is to remain. All our operations are done under aseptic conditions. The brow, eyelids, and face are carefully washed with a weak solution of carbolic acid, particular attention being given to the cleansing of the edges of the lids and the roots of the eyelashes, for this is a favorite hiding-place for noxious germs. The eye is then anæsthetized with a four per cent. cocaine solution, and the globe flooded with a solution of corrosive sublimate 1 to 5000. Great care is given to the thorough cleansing of the upper and lower conjunctival *cul-de-sacs*, by injecting the solution a number of times under the lids by means of a pipette. My own hands and those of the assistants are washed thoroughly in soap and water, and afterward dipped in an antiseptic solution of the sublimate or carbolic acid.

It is rare now that I use a blepharostat or speculum for holding the lids apart in doing this operation, though when I make a combined iridectomy I do.

The assistant holds up the upper lid by carefully applying his fingers to the edge of the lid and drawing it back on the ball, while with the fixation-forceps I draw the globe down and hold it firmly. I then take a Gräfe knife and make a section, detaching the cornea for about its upper third from the sclera. The puncture and counter-puncture are made just at the limbus—that is, at junction of the cornea with the sclera, and the attempt is always made to keep the section strictly in the limbus throughout its whole extent. This, however, is not always possible, for often there is a tendency of the iris to fall in front of the knife and in order to avoid cutting it the edge must be directed forward and as a result the apex of the section will lie to a greater or less extent in the clear cornea. I have not found, however, that this makes any material difference in the course of healing. The best results are, however, obtained when the section lies altogether in the limbus, and a small conjunctival flap is undoubtedly an advantage in conducing to a more speedy and firmer healing of the wound.

The section being completed, the anterior capsule of the lens is lacerated by a cystitome. This laceration of the capsule is done by some operators with the point of the knife in its passage through the anterior chamber from the puncture to the counter-puncture. I have tried it, but am better satisfied with the cystitome. In this operation almost everything depends upon the accuracy of the section, and it is important that the puncture and counter-puncture lie in the same plane perpendicular to the corneal axis, and to those who have never tried it, it is difficult to imagine how hard it is to estimate justly the exact position of the point of a knife when seen through the highly refracting cornea. It is much safer and easier to start the knife in a certain plane at the puncture and keep it up to the counter-puncture. When the anterior capsule is well lacerated a hard rubber spoon, which has been lying in an antiseptic solution of sublimate, is applied to the lower scleral margin and pressure is made backward and slightly upward causing the lens to rotate on its horizontal axis. Its upper edge, covered with the iris, then presents itself at the gaping wound, and a continuance of the pressure causes it to slip through the distended pupil and escape. This manœuvre is sometimes executed by making the pressure with the lower lid against the globe by means of the finger.

When the lens has been delivered, the lids are closed for a few moments to allow of an accumulation of some aqueous and to permit of a return of the prolapsed iris, which latter can be assisted by some slight rotary rubbing over the closed lid. When the lids are again opened it is frequently found that the iris has completely returned and the pupil is round and central. If it is black and there is no considerable amount of soft cortical matter remaining in the anterior chamber, the edges of the wound are closely inspected to see if they are clean and in apposition, and if they are found so, the eye is flooded again with the sublimate solution, the lids closed, a bit of thin cloth saturated with an antiseptic solution laid over them, the orbital cavity filled out with absorbent cotton and a light, four-tailed bandage applied over both eyes.

We have not adopted the new fashion, or rather the revived fashion of simply closing the lids with isinglass plaster. We think the light bandage more comfortable and safer. The bandage is removed at the end of twenty-four hours and the outer surface of the lids inspected, but the eye is not opened. This dressing is done simply for

the comfort of the patient. No possible good can come from an inspection of the eye itself. The wound is easily ruptured, even by the movements of the eye itself, when there will be a gush of aqueous and a prolapse of iris. If there is no great swelling of the lids it is only at the end of the third day that I gently pull down the lower lid and examine the condition of the conjunctiva, and usually put in a drop of atropine solution. If there is evidence of iritis or other serious inflammation sooner, as shown by great swelling of the lids and pain, the eye is opened at once and the difficulty treated vigorously by atropine, heat, anodynes, etc., and in case of suppuration of the wound by strong antisepsis.

There are a number of cases, however, in which the operation is not so ideal and simple as that just described. The iris does not return on accumulation of the aqueous, and when the lids are opened it is found lying in the wound. An attempt is then made to replace it. This is done by drawing a Bowman's probe, thoroughly aseptic, through the wound, the iris before it. And still the pupil may not become round, but remain oval. A rubbing on the outer surface of the closed lid will sometimes bring about the desired result. If not, then the effect of eserine should be tried. I find that many operators are afraid of eserine, thinking that it is liable to lead to iritis, and my own impression is that their fears are well founded and I never use eserine for assisting in a return of the iris when it can be avoided. If, in spite of all efforts, the iris refuses to remain, or, if it has been cut during the corneal section, the only thing to do is to excise it. And one of the claims of superiority of this operation is that the iridectomy can be done after the expulsion of the lens, if found necessary, as easily as before. As to washing soft corticalis out of the anterior chamber, I think it can be done often with impunity, but I believe too much meddling is not to be encouraged. It is done, however, by many good operators and it is perfectly true that under aseptic conditions we can do a great many things without fear which before we would not have dared to do.

We have done in this hospital, up to this time, twenty-four of these extractions without an iridectomy, and the general result has been so satisfactory that we deem ourselves committed to the operation until something better is offered. Only one eye has been lost, and that loss could not be, in justice, attributed to the operation. It was one of those cases which humble the pride of an operator and make him despair of obtaining absolute perfection in cataract extraction. The operation was perfectly smooth and thoroughly *secundem artem* and under the strictest aseptic precautions, and yet the whole cornea was lost through purulent inflammation which set in on the second day after the operation. In one other case there was closure of the pupil through iritis, which, however, can be improved by operation. In all the other cases the results were good.

ORIGINAL ARTICLES.

GLYCERINE ENEMATA IN INTESTINAL OBSTRUCTION.

By EDWARD R. MAYER, M.D.,
of Wilkesbarre, Pa.

Having noticed in The Medical News of January 28, 1888, an abstract of Dr. Althaus's article upon the treatment of habitual constipation by enemata of from half a drachm to a drachm of glycerine, I have adopted this simple plan in a number of cases, with general, if not with uniform success. It is a matter for surprise that no one had stumbled upon this expedient before.

In some instances I have substituted for the injection, the use of suppositories containing small quantities of glycerine, employing either conical gelloid capsules or the hollow suppositories of cocoa butter; occasionally, in adults, applying in succession two of the latter, when the single vehicle was not of sufficient capacity to contain a drachm of the agent. When the gelatine capsules were used several times, a slight amount of rectal irritation ensued. This did not occur after the insertion of the hollow suppositories, and with but one exception, the treatment resulted painlessly and agreeably in a more or less copious alvine evacuation within a half hour.

In one case, in which painful internal hemorrhoids coexisted with obstinate constipation, the enemata, continued daily during four days, not only produced more satisfactory evacuations than had been caused by the compound liquorice powder, but seemed so to lessen the hemorrhoidal hypertrophy and distress, that the patient considered himself more relieved by this means than he had been by a week's use of an ointment of iodol, cocaine, and extract of ergot, applied through a pile syringe.

But it is mainly to a different and extended use of this method that I now desire to call attention, believing that by this there is opened up to us a new therapeutic resource, which may become of inestimable value in certain cases in which our armament has hitherto been defective, as it unquestionably was in that which I am about to narrate.

Miss M., æt. sixty, long and safely past the menopause, of very vigorous constitution and prudent life, never the subject of any gastric, hepatic, or intestinal derangements, after an unusual exposure to low temperature and cold winds, was attacked in the night of February 1, 1888, with very acute and intense abdominal pains which seemed to radiate from the umbilical region. These were attended by slight but continuous rigors. To relieve these pains, she took in rapid succession the remedies she had at hand, a teaspoonful of Squibb's cholera mixture and six granules of morphia and atropia, each containing one-eighth grain of morphia and one-hundredth of atropia. When called upon to see her early in the morning of February 2d, I found her still suffering extremely, with a tympanitic abdomen, a very anxious expression, her face, however, flushed by the atropia, considerable nausea, a wiry pulse of 120, and a temperature of 102.5°. A hypodermatic injection of thirteen minims of an equivalent of Magendie's solution, was followed by complete relief from pain and by temporary cessation of nausea. After this, throughout the illness, the patient had no return of the lancinating and agonizing pains which

characterized its inception, while suffering throughout, from extreme abdominal soreness and tenderness. Hot turpentine stupes were now applied, and ten grains of antipyrin administered hypodermatically, with the effect of reducing the temperature within an hour to 100°. Minute doses of calomel and subcarbonate of bismuth were placed upon the tongue every half hour, and a quarter of a grain of cocaine hydrochlorate in a drachm of cherry laurel water, directed to be given upon the recurrence of nausea.

During the succeeding two days this plan of treatment was continued. The antipyrin was given under the skin whenever the temperature rose above 100°, and eight minims of the morphia solution injected nightly, or whenever the painful symptoms increased.

Nausea and vomiting were frequently present, but were somewhat kept in check by the injections of antipyrin and by the cocaine. No liquids, however, were retained, even iced peptonized milk with lime-water being rejected, and the patient being compelled to be content with sucking cracked ice.

As soon as the primary inflammatory symptoms seemed to abate, upon the morning of February 3d, efforts were made to relieve the tympany and constipation. These consisted in the insertion of a large flexible catheter as far up as the sigmoid flexure and of the injection through it, first of several quarts of warm saponified water, and later, at each time, a pint of an emulsion of turpentine with yolk of eggs. No relief followed the use of these; no escape of flatus occurred, and the returned enemata contained only some intestinal mucus.

In the meantime, while the pyrexia was being controlled by the occasional hypodermatics of antipyrin, the abdominal inflation was steadily and alarmingly increasing. Oppression, dyspnœa, gastric regurgitation, and slight singultus had developed, the pulse was running up and becoming more thready and uncertain, and all the symptoms indicated the dangerous condition of the patient, and threatened impending catastrophe.

The intestinal distention throughout the illness had been uniform and globular. No hernia existed, and the most careful examination made by Dr. G. W. Guthrie, who kindly gave me his counsel in this case, and by myself, had failed to elicit any evidence of appendicular disease, perityphlitis, or of indigitation or knotting of the intestines; the case being considered by us to be one of peritonitis with paralysis of the muscular coats of the bowels.

Upon the failure of terebinthinate enemata and of large injections of plain or of medicated warm water to give any relief in this case, all medicines administered by the mouth being now rejected, it occurred to me, fresh from the use with another patient of a small enema of glycerine, as recommended by Dr. Althaus, to extend and amplify his method in the now very serious condition of this patient. Accordingly, I at once proceeded to inject through a large flexible rectal tube, inserted at least seven inches, two fluidounces of warmed glycerine, with forty minims of tincture of belladonna added to it. The insertion and the injection produced no distress or immediate effect, and I left the invalid with directions to her nurse to cause the hips and knees to be elevated for a time. Upon my return after several hours, I found a greatly changed condition of affairs, comfort where there had been agony, and an anxious and pallid countenance replaced by beaming smiles and hopeful expression.

I was informed that within ten minutes after the administration of the glycerine enema, the patient felt a warm thrill and glow extending itself and permeating all through her intestines, followed by the vermicular movements which precede peristalsis, by audible and sensible displacements of gas, and finally by acute colicky pains. Within twenty minutes after the injection, there was an urgent call to stool, with the result of the escape of a large amount of flatus, and later, of a pint of semi-liquid evacuation of mingled yellow and green color, with some small scybalæ and a very pronounced odor. This evacuation was succeeded in an hour by another of a similar character. Considerable tympanites and tenderness still existed, but the abdominal distention was decidedly reduced, and the distress greatly relieved. The temperature, which had been kept depressed to about 100° by the antipyrin, soon fell to 99°, and the thready, jerking pulse of 120, had descended to 100, and the next day was not above 90, becoming rapidly soft and full. The nausea abated, and in a few hours disappeared and did not return.

Enemata of warmed glycerine to the extent of two ounces each, without the belladonna, which did not seem to have been a factor in the beneficent action of the injection, were now administered night and morning during the next three days, each one resulting in a copious fecal evacuation, at first liquid, and then formed. The temperature varied during several days between 99° and 99.6°, the pulse soon dropped to 80, the tenderness gradually disappeared, and the distention slowly melted away. Milk punch, beef-tea, and revalenta arabica were greedily taken in small quantities, retained and digested, and upon the ninth day of the illness the patient, while feeble, was entirely convalescent, a salutary diarrhœa having set in after the enemata were discontinued, and soon ceasing. The only drug treatment employed after the symptoms improved, was a single very small dose of a saline laxative and a nightly hypodermatic of six minims of morphia solution, to secure rest.

In regard to the action of glycerine in stimulating the intestinal canal after having been brought into contact with the lower rectal mucous membrane, Anacker's explanation of the effect is that the affinity of glycerine for water, withdraws the latter from the tissues, thus causing hyperæmia and irritation of the sensitive nerves of the rectum, which in turn lead reflexly to powerful peristaltic contractions. There is doubtless a portion of truth in this view, but in such a case as I have described, there is probably a further action of the remedy for which this alone will not account.

A peculiarity of the conduct of glycerine is that its physical action, when placed in contact with mucous surfaces, is such as to enable it to overcome

and annul the physiological action of the component mucous and submucous tissues, permitting us by its use to modify these in a singular manner. I suppose that every medical man has noticed that the nasal insufflation of glycerine, or its application to the uvula, tonsils, or pharynx, is immediately followed by laryngeal distress, cough, and profuse laryngeal and pharyngeal expectoration.[1] The fact must be that partly owing to its hygroscopic affinity, so great is the extensibility and permeative power in all directions along a mucous surface, of pure glycerine, that it not only diffuses itself along and beyond the original seat of its application, but that it inhibits the natural movements of the ciliary bodies, where these exist, as in the nasal and throat cavities, projects itself in a direction the opposite of their progressive current, paralyzing their activity, and so continues to do, until exosmosis has sufficiently diluted it to prevent its further influence.

In the case which I have described, I can scarcely believe that the direct stimulation of the lower rectum by the glycerine enemata could have been so perfectly conducted to the plexus myentericus as to cause such violent dysperistalsis in the ileum and jejunum as speedily occurred in them, and I consider it probable that portions of the injected glycerine rapidly passed the sigmoid flexure and became diffused throughout the colon and possibly through some folds of the small intestine. The result of such contact would be, not immediate and direct hyperæmia of the surfaces exposed to it, but, first, anæmia of the same with irritation caused by the exosmotic withdrawal of the watery contents of the capillaries and submucous tissues, along with a rapid increase of the liquid contents of the parched intestines, and then as succeeding the shock, subsequent hyperæmia, increasing afflux of blood and vital action, with a more extended basis for reflex stimulation of the great splanchnic centres, resulting in powerful peristaltic contractions upon tubes rendered, by the presence of the then diluted glycerine, more full of liquid contents, and offering sufficient resistance to the contracting muscular coats to work upon. *Per contra*, however, it is but just that I should state what I omitted to mention, that after the established success of the first injection passed through a rectal tube, the subsequent ones were administered through a two ounce hard rubber syringe, and seemed then, the first difficulty overcome and entrance effected, to be as efficient as that which was injected higher up the rectum. But these latter injections were not followed by the intestinal thrill and glow which characterized the action of the first one used.

In using these injections, it must be borne in mind that the glycerine should be heated to at least 100°, as the remedy, when cold, cannot be readily drawn into a syringe.

If glycerine, injected by the method described, does really penetrate and permeate the upper colon or even the small intestine, it remains to be ascertained whether drugs combined with it as their vehicle, would measurably remain in the site to which they would be conveyed, or would be too completely washed away and extruded by the pouring out of large quantities of liquid and by the violent expulsive efforts of the muscular coat of the intestines to exert their specified influence. Should it be that any considerable portions of such drugs would remain *in situ*, it is manifest that an improved method of internal medication is near at hand, and that such drugs as antifebrin, antipyrin, aloin, belladonna, calomel, croton oil, colocynth, ergotin, hydrastia, hamamelin, naphthalin, physostigma, the terebinthinates, and even nitrate of silver, and some of the germicides may be introduced by an entrance into portals hitherto closed to them excepting by a devious journey through the ordinary avenues. He would be a rash man who, with our present knowledge, should attempt to sterilize typhoid bacteria by a direct attack upon the agminate glands, but stranger things than this have happened, particularly of late, in the direction of gaseous rectal medication.

[1] I have often taken advantage, successfully, of these properties of glycerine, by emptying, by pressure, upon the rima glottidis, a soft probang sponge saturated with the liquid, in cases of true croup. This treatment has frequently proved to be an efficient means of aiding in the softening and dislodgement of the false membranes, and it always provokes a very violent and explosive cough. In such cases, glycerine in the form of spray can only be employed when diluted, and so rendered incapable of attracting more liquid from the parts to which it is applied.

THE DIETETIC TREATMENT OF THE GOUTY DIATHESIS.[1]

By WILLIAM H. DRAPER, M.D.,
PROFESSOR OF CLINICAL MEDICINE IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

Before entering upon the special consideration of its dietetic treatment, it is important that we should define the gouty diathesis. We shall arrive at a clearer comprehension of its meaning, if we define the terms "gouty" and "diathesis" separately, and diathesis first.

The term diathesis, like temperament, hides more than it reveals, but it is, nevertheless, a useful exponent of the common recognition of a supposed underlying likeness of physical constitution in persons who are inclined to special and recurring aberrations from the state of health. The many and varied influences exerted by environment, food, habits, and diseases, have so modified the primitive physical condition of man as to impress upon it certain broad and well-defined derangements of

[1] Read before the Medical Society of the State of New York, Feb. 7, 1888.

normal function and structure. The tendency to exhibit these derangements is sufficiently though somewhat vaguely indicated by the term diathesis, or disposition, its literal meaning. We qualify the term according to the prevailing idea of the determining cause of the particular varieties of health disorder. Thus we speak of diatheses caused by climatic influences, by diet, by special vices or specific diseases. We observe in the victims of these diatheses certain derangements of functions and certain weaknesses or vulnerability of tissues, which may descend in families and perpetuate their likeness through generations. We may say that scarcely any one is free from these diathetic states in one form or another. There are few persons, for example, whose physical constitution has not been modified by atmospheric or telluric influences, and fewer still, probably, who have not had a more or less permanent effect produced upon their organization by ancestral or personal habits of eating and drinking. Climate and diet, indeed, may be said to be the two causes of diathetic derangements of physical health which are the most universal in their operation. Of these the one with which we are concerned is that which proceeds from the habits of eating and drinking.

By a sort of common consent the term "gouty" has been given to the principal diet diathesis. In defining this term we must ignore any allusion to the theories of gout, and simply indicate, briefly, the broad and characteristic features of the gouty diathesis as observed in the functional derangements and structural changes to which its victims are subject. Of the functional disturbances, taking them in the order of their frequency we must mention first the fermentative indigestion provoked by the carbohydrates—the sugars and starches, and their derivatives, wine and beer. This indigestion is marked by gastric acidity, flatulence, and pyrosis. Next in order of the functional derangements, and not always, nor necessarily, in connection with gastric symptoms, are those of the hepatic function, constituting what is commonly called biliousness or the lithæmic state. This manifests itself by constipation, diarrhœa, and hemorrhoidal congestion, and especially by changes in the quantity and quality of the urine; in excess of acidity, in the presence of glucose and of crystalline deposits of uric acid, urates, and oxalates. Frequently associated with these conditions are diverse nervous disturbances, some central, some of reflex origin. Visceral neuroses, trigeminal, occipital, intercostal, lumbo-abdominal and sciatic neuralgias, vertigo, numbness, itching, burning, and other perversions of sensation are often symptomatic of the gouty diathesis; to these may be added the psychical disorders, hysteria and hypochondriasis.

It would be impossible, in the limits of this paper, to do more than indicate in the briefest manner the tissue derangements which occur in this diathesis. They may be conveniently classified as affecting the tegumentary structures, the skin and mucous membranes, and, through the connective tissue and the fibrous structures, the arteries, the viscera, the locomotor apparatus, and the nervous system. The liability of gouty persons to transient vasomotor derangements, and to more or less persistent inflammatory processes in the skin and mucous membranes, is too well recognized to require comment. The cutaneous erythemas, eczemas, seborrhœas, the catarrhs, pulmonary, gastro-intestinal and genito-urinary, which are associated with this diathesis are much more common than is generally believed.

The fibrous tissue lesions are observed in thickened arteries, in valvular diseases of the heart, in cirrhosis of the lungs, liver, and kidneys, in acute and chronic inflammations in and around the joints, and in perineuritis. In making this statement in regard to joint affections, I am aware that it assumes more than is admitted by many authorities on the pathology of the joints. If the presence of tophous deposits is regarded as essential to gouty inflammation, this anatomical evidence of the gouty nature of rheumatoid arthritis and nodi digitorum is certainly often wanting; but, if we regard the excess of uric acid in the blood not as the essential cause of gouty inflammation, but rather as one of the epiphenomena of the gouty state, and as the consequence of defective excretion; and, furthermore, if we take into consideration the revelations of the personal and family history in gouty diseases, we will frequently find abundant proof of the kindred nature of lithæmic gout and the more common forms of rheumatoid arthritis. It is certainly often impossible to differentiate them clinically, and, so far as a similar origin can be inferred from their reactions to treatment, there is no lack of evidence of their relationship in this respect.

The common and varied nervous derangements of gouty persons have already been referred to, in connection with the numerous functional neuralgias and paræsthesias associated with gouty indigestion. In addition to these there are certain definite persistent neuralgias and perversions of sensations which are probably dependent upon perineuritis. The most common of these are the sciatic, cervico-brachial, intercostal, and lumbo-abdominal neuralgias; numbness, formication, itching, vertigo, and the like.

There is one other organic derangement which my experience leads me to believe is a common one in gouty families, and that is anæmia. The tendency to blood deterioration is especially noticeable in women who inherit this constitutional vice. We have presented this brief and imperfect sketch of the gouty diathesis because it seemed an essential preliminary step to the consideration of its dietetic

management: for it is clear that if this diathesis has its origin in habits of eating and drinking, the rational basis of treatment must involve a serious modification of these habits by the regulation of the diet.

Gout may fairly be regarded as a disease of modern civilization, and as presenting its most typical and varied manifestation in the more advanced communities of the civilized world. It has been said that had mankind continued to be vegetable feeders, and never known the use of wine or beer, we should have had no experience of gout. This is probably a very partial and imperfect statement of the origin of this widespread disease, inasmuch as typical gouty arthritis has been observed in the herbivorous animals. There are doubtless many factors in the production of this diathesis, relating to quantity as well as quality of food, to the relations of food to work and habits of life, indeed, to all the circumstances which affect the complex metabolism of food and the evolution of vital energy in the process of nutrition.

It is a common belief that gout is largely the result of excessive indulgence in animal foods, and yet, as has been already remarked, there is no more conspicuous characteristic of gouty persons than their feeble capacity for the digestion of the carbohydrates and their derivatives. It is a fact of daily observation that the disorders of digestion, with all the attendant derangements which belong to the gouty diathesis, are especially determined and aggravated by the too liberal use of sweets, starches, wine and beer. It is the recognition of this feeble capacity for the conversion of the carbohydrates, which, I believe, suggests the guiding principle in the regulation of the diet of gouty persons. It is important to note that this is in diametric opposition to that regulation of the diet which is based upon the theory that uric acid is the essential cause of gout. This theory makes the exclusion of nitrogenous foods the special feature of an anti-gouty diet. But while a diet largely composed of carbonaceous foods is opposed to the generally accepted theory of gout production, I believe that clinical experience amply demonstrates that it is the most efficient cause of the lithæmic state and the protean miseries of the gouty diathesis.

More than fifteen years ago while studying the relations of the benign form of glycosuria to gout, I was impressed with the frequent association of the saccharine disease with the characteristic symptoms of the acid dyspepsia of gouty subjects, and not only this but with the actual correlation of gout and diabetes in different members of gouty families and frequently with the association of the two diseases in the same individual. I was led to this observation largely by the impressive lectures of Bence Jones on the "Applications of Chemistry to Pathology and Therapeutics." A large clinical experience has confirmed me in the belief that the theory of suboxidation explains better than any other the etiology of glycosuria and gout, and that in both these diseases the consequences of defective oxidation are first and most markedly observed in the digestion of the carbohydrates.

I have thus referred to glycosuria as belonging to the family of gouty diseases because the diet which is prescribed for this malady represents the extreme degree to which it may be necessary to carry the exclusion of non-albuminous foods in some forms of gouty disease. If we consider the ordinary anti-diabetic diet we find that the order in which the non-nitrogenous elements are excluded in glycosuria is first the sugars, including fruits, wine, and cider, and secondly, starches, including beer. The same order has often to be observed in the regulation of the diet of gouty persons. The intolerance of sweet desserts, of fruits, raw or cooked, and especially of wine, is one of the most frequent indications of this diathesis and in decidedly gouty persons indulgence in these articles of diet is pretty certainly followed by the characteristic dyspeptic symptoms, or by some of the nervous disturbances which I have mentioned. It is not uncommon for gouty persons to present special idiosyncrasies in regard to certain articles of diet of this class. This is notably true of particular varieties of wine and fruits, muscular and articular pains and even articular inflammation being promptly provoked by them.

The intolerance of considerable quantities of farinaceous foods and beers, while perhaps less marked than that of sweets and wine, is still often a pronounced characteristic of gouty subjects. They give rise to indigestions, which are especially apt to be accompanied by mucous catarrhs and cutaneous eruptions. The evil effects of excessive quantities of farinaceous foods are often observed in the children of gouty parents, in whom they engender an abnormal accumulation of fat, catarrhal affections, eczemas, and not infrequently lithæmic neuroses.

While the restriction of starchy foods seldom requires to be so absolute as that of sweets in the diet of gouty disease there is no question as to the value of their complete exclusion in certain cases. The strict enforcement of a purely nitrogenous diet in some cases of rheumatoid arthritis, and especially in aggravated forms of gastric catarrh, is unquestionably a therapeutic measure of conspicuous value. The utility of a diet of meat in these cases has met with a certain degree of popular recognition through the success of the so-called "Salisbury treatment," and this very fact has perhaps retarded a more general acceptance of its value by the profession. My own experience has furnished many examples of chronic arthritis, gastric catarrh, and lithæmia which have proved rebellious to all treatment while farina-

ceous foods were allowed to form an element of the diet. The cases, I think, are few where it is necessary to exclude them entirely, but I am sure they are very numerous where the greatest benefit is derived from reducing them to a moderate amount of bread, and allowing a variety of animal food and green vegetables. The hydrocarbons, butter, cream, cheese, nuts, marrow, and the fat of meats may be allowed in moderation, and serve to replace the carbohydrates in an ordinary mixed diet.

As the most pronounced peculiarity of the victims of the gouty diathesis is the prompt reaction which they present to wine and beer, it follows that the exclusion of these beverages, as articles of diet, must be insisted upon. This is often a difficult injunction to enforce. There is so strong a popular and professional prejudice in favor of fermented liquors as articles of diet that one can hardly prohibit the use of them, under any circumstances, without being regarded as a crank. In spite, however, of the generally received opinion that ardent spirits are responsible for all the physical evils of intemperance, I have long been inclined to believe that the fermented preparations of alcohol are equally, if not more productive of functional derangements, and even of structural lesions. Certainly, if alcohol is allowed at all, very dilute spirits or dry champagnes are the only forms, as a rule, which victims of gout can use with impunity.

I would also repeat the caution which I have suggested in regard to fruits. I believe it is often very important to insist upon the exclusion of fruits from the diet of gouty persons. This is another injunction which is so opposed to popular and even professional sentiment that it is frequently difficult to enforce it.

I have thus sketched very briefly, the principles which I believe should guide us in regulating the diet of persons presenting the general features of the gouty diathesis. There are many details in this regulation based upon the more or less pronounced intensity of the diathesis, upon its particular manifestations, and upon the special idiosyncrasies which gouty persons exhibit in regard to certain articles of diet which are very important and which necessarily make each individual case a study by itself. These details I have not time to consider. It will be observed that the general principles which I have stated are based upon the recognition of the fact that gouty subjects have a limited capacity for the digestion, and conversion into the different forms of vital energy, of the carbohydrates. There seems to be no better way of expressing this cardinal peculiarity. How this departure from what has generally been regarded as the primitive habits of man as a vegetable feeder, has been brought about, it is not our purpose now to inquire. I would simply remark in regard to this point, that it is probable that the exigencies of modern civilized life have come to demand a finer adaptation of diet to occupations and mode of life than has hitherto been considered necessary or practicable. The relations of food to work, or to the diverse developments of human energy, and the regulation of diet according to special physical defects, constitute some of the most interesting and important problems that can engage our attention. Science has long since arrived at some definite conclusions on these questions in their application to the training of athletes, the animals which serve and amuse us, but beyond this it has not shed much light. It may be said, however, that it is probable that the carbodydrates are the foods best adapted to the evolution of the greatest and most prolonged muscular energy, and that they are most perfectly consumed and in the largest amount by those whose lives are spent in mechanical work and under favorable conditions in the open air. There is also good reason to believe that brain workers, and those whose lives are passed indoors, and in more or less physical indolence, require, for the best development of their energies, a diet that is rich in albuminous foods.

OMPHALECTOMY FOR STRANGULATED UMBILICAL HERNIA; DEATH.

By W. W. KEEN, M.D.,

PROFESSOR OF SURGERY IN THE WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA, SURGEON TO ST. MARY'S HOSPITAL, ETC.

MRS. G., æt. fifty-six, a short, very fat woman, abdominal girth fifty-four inches, had had five children. After the birth of her last child, eighteen years ago, an umbilical hernia showed itself, of the size of a small pear. She has worn no truss. She has had repeated attacks of intestinal colic transient in character; but no other inconvenience, nor had the tumor enlarged. Within a year she has had several bad falls, but no special symptom referable to the tumor. The last occurred a week before the present sickness. At 5 A. M., January 21, 1888, without apparent cause the tumor became painful and inflamed. She sent for Dr. Emma E. Musson, who treated her symptomatically as seemed to be called for. Her bowels were freely opened that morning. She vomited, repeatedly, simple bilious matter.

I first saw her January 23d, at Dr. Musson's request. I found the tumor inflamed and softened over about one-third of its area, the rest being hard and doughy. It was not fluctuating and was entirely dull on the most careful percussion. It was very tender and admitted of but little attempt at taxis, which was unsuccessful. Simple antiseptic dressing was therefore applied lest it should open spontaneously. Morphia and atrophia relieved both the pain and the vomiting. The diagnosis was an irreducible old omental hernia with, probably, a recent enterocele in addition.

January 24. Her symptoms have somewhat ame-

liorated. The temperature has not risen above 99.2°. The vomita have become brown and thicker, but absolutely without fecal odor. The tumor has kept at the same grade of inflammation, but has softened over all its surface without bursting. Its tenderness has decidedly lessened, so that it can be easily handled, but the hernia cannot be reduced. The hypodermatic needle showed the liquid contents to be bloody serum and not pus, and with no fecal odor. Around the navel, over two fingers' breadth, is a ring of hardening, but no tenderness or other evidence of peritonitis. Her vomiting has been less frequent, only two or three times a day.

26th. The same conditions obtain ; no further rise of temperature ; moderate purgatives had produced no evacuation. An exploratory operation was decided on for the next day, unless she was decidedly better. Dr. Musson examined the urine, finding it normal, no sugar or albumen.

27th. Last night distinct fecal vomiting set in, and this morning the matters vomited were really liquid feces and very offensive. At 9.45 A. M. I operated with ether and strict antisepsis. I incised the sac, when a few drops of odorless bloody serum escaped and a mass of healthy uninflamed omentum came in view. This was adherent at almost every point, but most of the adhesions could be broken up with moderate force. Deep down in its centre I found the ring of the umbilical opening. The belly wall was three inches thick, and the tip of my forefinger just reached the ring. Through this protruded a small coil of intestine which was surrounded and covered in by the omental fat. The intestine was a little congested, but not dark in color, nor soft in consistence. By loosening its moderate adhesions I was able to reduce it. The ring then was found to be as large as the forefinger, with a firm thickened rim. I tried then to reduce the omental protrusion, but its adhesions at the mouth of the sac were too firm.

The umbilical opening was so deep, and the ring so thick and unyielding, that it was hopeless to attempt its closure ; and to leave it as it was, so thoroughly open and so inaccessible to external pressure through so thick an abdominal wall, was but to invite a speedy return of the hernia. Accordingly, I at once performed omphalectomy, a procedure I had previously decided upon in case I should operate, unless circumstances should forbid. I made a vertical elliptical incision six inches long, including the umbilicus at its centre, only one vessel requiring ligature. When the abdomen was opened, excepting the hernia, I saw nothing abnormal and I did not explore it. I tied and divided the omentum adherent to the umbilical opening and immediately proceeded to close the abdomen. I used four rows of sutures, one to the peritoneum, one to the muscular wall which was very thin, a third to the enormously thickened fatty layer, and the fourth to the skin. The first three were of chromic catgut, the fourth of wire. Sublimate gauze and a binder completed the dressing.

She passed the night in fair comfort, with a little morphia, but her temperature at 9.30 P. M. was 100.8°, at 4 A. M. 103.4°, and in the morning at 10.30 had risen to 104°. At 4 A. M. she vomited once, but it had only a faint fecal odor. At noon her temperature was 103.6°, and as Dr. Musson had already given her 20 grains of quinine by the rectum, I advised 15 grains antipyrin. She had no pain. She was somewhat stupid, and her general condition was far from satisfactory ; gaping, sleepy, and with a quick and feeble pulse. She was also somewhat jaundiced.

At 2.15 P. M. she took the antipyrin. At 2.45 P. M. she was partially collapsed, the hands and feet cold, pulse quick and thready, and she was nearly unconscious, temperature 102.4°. This condition gradually deepened in spite of external heat, brandy, digitalis at short intervals by the hypodermatic syringe, etc., till 7 P. M., when she died.

Post-mortem nineteen hours after death by Dr. Musson.

Result of Post-mortem. — The wound showed no signs of uniting. The peritoneum, omentum, and transverse colon were an adherent mass, dark in color.

The *bowel* just above the cæcum, and the part found in the hernia were gangrenous in appearance.

The *stomach* contained a pint of fluid fecal matter, which formed a coating to the whole lining of the stomach. The stomach and bowels were distended with gas. Decomposition had been rapid.

The *gall-bladder* was filled with stones.

The *right kidney* contained a large cavity filled with urine and numerous small stones. Little or no kidney substance was left.

The *left kidney* was large, flabby, and friable.

Spleen, substance friable.

Liver, under surface grayish-green.

Signs of an old *perityphlitis* were found.

The *chest* was not opened.

Remarks.—The operation above detailed I had intended to perform, some years ago, for the radical cure of a large non-strangulated umbilical hernia, but circumstances made it impossible.

So far as I know, this is the second case of umbilical hernia treated by Omphalectomy, and, indeed, until Dr. Wm. J. Taylor made a necessarily hasty search through the literature of the subject, I thought it the first. In the *Medical Record* for 1866, p. 73, Prof. H. R. Storer describes the case of a woman upon whom he performed a precisely similar operasion, Feb. 4, 1866. She was forty-one years of age, and had suffered from ascites, of hepatic origin, for many years. For this she was tapped forty-five times, not only to relieve the ascites, but, at last, to prevent actual rupture of the umbilicus. For the same reason as myself he made a long incision (seven inches), so as to avoid the puckering and plaiting of the margins, if a simple, circular, or short oval incision had been made. At the end of twenty-four hours she was doing well, when from a sudden fright, which, in her enfeebled condition she could not resist, she "rapidly sank and died of secondary shock, thirty-eight hours after the operation." At

the autopsy no peritonitis was found. The gall-bladder was distended with calculi.

In these days of abdominal surgery it is rather curious to see the serious storm of criticism that the case aroused—so serious that Prof. Storer deemed it needful to enter into an elaborate defence of it—a defence which subsequent events have fully indorsed. Indeed this is one of the earliest cases of a purely exploratory laparotomy that I know of, and is most creditable to Prof. Storer's foresight. November 21, 1865, two months before the appearance of the umbilical distention, and two and a half months before the Omphalectomy, he made a distinctly exploratory operation to clear up the diagnosis; but as, with a caution due to the then prevailing sentiment in the profession, he only explored the pelvis, he did not discover the nature of the hepatic trouble. She was entirely well, without any bad symptom, in five days.

In the *Trans. Amer. Surg. Assoc.*, vol. 7, 1887, a case of Dr. Michael's will be found in which for a non-strangulated, median, ventral hernia he did a precisely similar operation with a favorable result.

Umbilical herniæ are generally operated upon only by ordinary herniotomy, followed in some cases by ligature of the sac or suture of the ring. I believe, in spite of the unfavorable result of these two cases, a result incidental and not fundamental, that Omphalectomy in cases of strangulated, and often of non-strangulated, umbilical herniæ will in time prove to be the proper procedure, especially in cases like my own, where the immense thickness of the belly wall makes any operation on the ring itself difficult if not impossible. The tendency of modern surgery is decidedly toward the radical cure of hernia, and the comparative safety of laparotomy, as now done, makes such a radical operation in umbilical hernia peculiarly wise.

My only regret in the present case is that I did not do the operation earlier, before the patient's strength was exhausted, and before the fecal vomiting set in. To this last I attribute her death. To fill the stomach of a healthy person with liquid feces would be perilous enough, but in the case of a patient already sick for six days it was more than she could bear, and her system was probably poisoned by it.

The condition of the kidneys was not suspected before death, although the urine was examined. Doubtless their unsatisfactory condition, as well as that of the liver and spleen, contributed somewhat to the ultimate result. The normal amount of water was secreted and drawn by the catheter after the operation.

The operation itself, in spite of the excessively thick abdominal wall and big, flabby belly, was very easy in its technique. Even in so large a belly no trouble was found in dealing with the intestine. Had the patient's condition been good, I have every reason to believe it would have been entirely successful.

How far the antipyrin may have contributed to the fatal result is open to question. The sudden and great rise of temperature seems to me to mark the septicæmia which would naturally be followed by speedy collapse. It was too sudden and too great to result from the operation alone, and the want of union in the walls of a healthy wound, and the gangrenous process in an intestine which was in far from an unfavorable condition at the time of the operation, seem to point distinctly toward septicæmia from fecal absorption.

The antipyrin probably did precipitate the impending collapse and hasten the lethal result.

The absence of fecal odor in the fluid of the sac is worthy of note, and is accounted for by the separation of the fluid from the protruded intestine by the omentum. This produced a doubt as to whether any intestine was caught in the hernia until the fecal vomiting settled that fact. Before that the temperature and all the local signs pointed rather to an old inflamed omental hernia only. Had the liquid shown a fecal odor I would have operated earlier, and I believe with a happier issue.

LEPROSY AFFECTING THE EYES.

BY CHARLES W. KOLLOCK, M.D.,
OF CHARLESTON, SOUTH CAROLINA.

THE opportunity of seeing and treating leprosy does not fall to the lot of many physicians in this country, and books upon ophthalmology written here and abroad either mention it incidentally or not at all. No new light will be thrown upon its etiology or treatment, but a simple description of the effect of the disease upon the eyes, and the treatment pursued, is the purport of this paper.

Though but one case has come under my notice it is a well-known fact that the disease has existed in sporadic cases in this neighborhood for years. It has not spread, nor has it been inherited, so far as can be ascertained. In but one instance to my knowledge has more than one member of the same family been affected. In this case a lady and her niece were both diseased. The latter, as soon as the disease became known, at once put herself under treatment and the disease apparently was in abeyance. She died quite suddenly of heart trouble.

In May, 1886, Mrs. —— was brought for consultation concerning her eyes. She had been sick about six years, and the disease was a pronounced case of lepra tuberosa and anæsthetica, the tuberosities and anæsthetic spots both being present. The leonine countenance was not at that time so well marked as it had been some months previous, but even then there was a heavy, wrinkled and distorted appearance. Under treatment consisting at times of Chaulmoogra oil and Hoang-nan she had im-

proved slightly, the tuberosities disappearing to a considerable degree, but leaving the anæsthetic spots.

She was very miserable, with poor appetite, suffered from insomnia, was exceedingly nervous, and with vision so defective that it was with difficulty she could find her way about the house. This difficulty was increased by the loss of the tactile sense of the fingers and hands, which were swollen, especially around the joints, and lacked sensation to such an extent that she was badly burned by a stove without being at first aware that it was heated.

Her eyes became affected about two years prior to her visit. Vision was as follows: R. E. $\frac{1}{cc}$; L. E. $\frac{10}{cc.}$ There were photophobia, lachrymation, narrowing of the palpebral fissures, thickening of the lids, ocular and palpebral conjunctivitis, and keratitis. The corneæ were hazy and covered with facets, and near the centre of each was a whitish spot about three mm. in diameter. Small blood-vessels ran from the conjunctivæ to these spots, which were not like the true pannus, but lighter in color and more deeply set in the corneæ. The irides were dull, pupils not dilated, and reacting but slightly to a strong solution of atropine. Apparently there were no posterior synechiæ, for the pupils dilated regularly, and whether this inactive condition was due to non-absorption of the mydriatic by the corneæ, or to a stiffened and infiltrated state of the irides, is a matter of conjecture, but probably both contributed. Owing to the hazy condition of the corneæ no intraocular examination could be made.

Having never seen a case of lepra, I was inclined to be sanguine of improving the condition of the eyes. Attention was directed to the lids, cornea, and iris. For the lids all known collyria, not irritating to the cornea, were used, and solutions of nitrate of silver carefully applied. Atropine at first allayed the pain and moderately dilated the pupils (beyond a certain point they would not go), but after a time it set up violent inflammation, and was discontinued. Eserine was without avail, and the ointment of yellow oxide of mercury and calomel failed to accomplish any good. Jequirity (three per cent. solution) was used on several different occasions, intense inflammation followed as usual, promptly subsided when the applications were stopped, and the condition of cornea and lids remained unchanged.

Iridectomy was performed upon the worse eye (right), and though there was at this point comparatively clear cornea, no improvement in vision followed. The lens seemed fairly clear through the hazy cornea. Finally both spots were deeply cauterized by the galvano-cautery, and this alone seemed to better the conditions a very little by causing slight contraction of the spots and smoothing of the surfaces.

After this treatment was discontinued, as the patient and family were averse to more active measures which would have been more extensive, including cauterization and perhaps extraction of the lens, which has of late become distinctly cataractous.

The size of the spots has not materially increased, but vision has gradually grown worse, she being able to distinguish the movements of a hand before the eyes, but cannot count fingers. Secondi, of Genoa, reports several cases where vision was improved and the disease apparently checked by excising the spots from the cornea, and performing iridectomy.

It is unfortunate that no ophthalmoscopical examination was possible, for it is believed that the disease has extended to the retina and choroid, as no improvement in vision followed the iridectomy, at which time the cornea and lens were not opaque.

Though treatment has been unavailing, and the condition of the eyes, as far as vision is concerned, has gradually become worse, still, I am inclined to think that had a thorough and repeated application of the galvano-cautery been made in the beginning of the attack the result would have been different.

MEDICAL PROGRESS.

The Antiseptic Values of Chlorides, Nitrates, and Sulphates.—In a recent number of the *Journal of the Society of Chemical Industry* (Vol. vi. No. 11), Mr. C. T. Kingzett, F.C.S., records the results of some experiments which he has conducted in order to determine the relative extent to which certain metallic chlorides, nitrates, and sulphates retard the appearance of mould on flour-paste, and putrefaction in extract of beef respectively. The general bearing of the results is to show that the salts of the alkalies and alkaline earth, excepting magnesium sulphate, appear in many instances to promote and never to retard the growth of mould. The compounds of zinc resemble those of the alkaline earths in their action. On the other hand, the salts of iron, tin, lead, and aluminium exercise distinct but not very powerful effects in preventing the appearance of mould. The chloride of lead is, however, more active, whilst the most efficient are the chlorides of mercury and copper. In preventing the putrefaction of extract of beef, the chlorides of mercury and copper were also the most effective; whilst chloride of zinc was more and chloride of lead less active than in retarding the growth of mould on flour-paste. The value of the investigation is very much reduced owing to the experiments not having been conducted on the modern lines of bacteriological research. Thus the various test-glasses containing the experimental media were allowed to become accidentally infected from the air to which they were exposed, instead of being all inoculated either with some definite microörganism or with some definite mixture of microbes, as is now invariably done in experiments of the kind.—*British Medical Journal*, January 21, 1888.

Poisoning from Boric Acid, in Surgical Practice.—Dr. Spencer, of St. Paul, reports the following case, in the *Northwestern Lancet* of January 15, 1888.

A short time since a woman was admitted to the City Hospital with syphilitic necrosis and caries of the bones forming the ankle-joint. October 2d, he removed by scooping, scraping, etc., parts of the lower ends of the tibia and fibula, and nearly all of the astragalus. The

sinuses in the soft parts about the joints were scraped as clean as possible, the cavity was washed out with a weak bichloride solution, and packed with large crystals of boric acid, probably something over half an ounce being used. Although the wound was very foul-smelling at the time of operation, it was left undressed for a week and was then found nearly free from odor. Most of the acid was still undissolved in the cavity, but a small portion having been absorbed. It was washed out and dressed in the same way as before and left for another week. During this time, fourteen days, her health, appetite, and general condition were good. She then began to lose her appetite, and in a short time had nausea and vomiting, which grew progressively worse, so that, finally, nothing could be retained by the stomach. Lime water, counter-irritation, and cold to the epigastrium, morphia, ipecac, and all the various anti-emetics were used in vain. Her other symptoms were restlessness, insomnia, the little sleep she did get being very disturbed, almost constant hiccough, great weakness and emaciation, and a very marked cardiac weakness. Although her pulse was very weak, there was none of the compensating rapidity which generally occurs in heart failure. She had a rather severe coryza, the conjunctivæ were very red and inflamed, there was marked inflammation of the fauces and pharynx, some bronchitis, and an acrid discharge from the anterior nares. Her tongue was red, glazed, and cracked. There was a very well-marked papular erythema, the papules nearly coalescing over the face, neck, arms, and upper part of chest. These symptoms came on gradually and grew worse for three days, at which time she was very weak, though she had taken considerable nourishment by rectum. The dressing was then changed, and the symptoms here noted began to disappear, although it was ten days before she was as well as before they began.

The Treatment of Acne.—Unna, in the *Monatshefte für praktische Dermatologie*, No. 1, 1888, advises the use of the following formulæ, to be applied at night:

Ung. zinc. benzoat.	86 parts.
Sulphur. præcip.	10 "
Terræ siliceæ	4 "

Or

Ung. zinc. benzoat.	80 parts.
Resorcin. puriss.	10 "
Terræ siliceæ	10 "

For use during the day either of the following lotions may be employed:

Resorcin.	2 to 5 parts.
Glycerin.	1 part.
Aq. flor. aurant.	20 parts.
Spiritus	80 "

Or

Hydrarg. bichlor. corros.	$\frac{1}{20}$ to $\frac{1}{2}$ part.
Glycerin.	1 part.
Aq. flor. aurant.	20 parts.
Spiritus	80 "

[3] ***Typhoid Bacilli and Boiling Water.***—In order to test the destructive power of boiling water on typhoid bacilli, Dr. Vilchur, of St. Petersburg, made a number of pure cultures in broth, keeping them in a thermostat for two days at a temperature of about 92° F., and then mixed them with known proportions of boiling water, immediately afterward sowing the mixtures in jelly. The results showed that, when the volume of boiling water equalled that of the culture, the bacilli were partially but not wholly destroyed. When double the volume of boiling water was used, the bacilli were all killed. From experiments with typhoid stools, he found that all the bacilli, however numerous, were invariably destroyed by the addition of a volume of boiling water equal to four time that of the stool. In this way he suggests it will be easy to disinfect with certainty all the dejections of typhoid patients.—*Lancet*, January 14, 1888.

Impaction of a Coin in the Larynx; Laryngotomy; Recovery. Archambaud reports the case of a man, aged twenty-three, who came to one of the Paris clinics suffering from prostration in a marked degree. Two days previously he had swallowed a 50 centime piece, which had lodged in the larynx. He had been suffering from dyspnœa, could take food with the greatest difficulty, and was on the verge of exhaustion.

Examination revealed the coin lying upon the lower vocal cords; it was enclosed from right to left by the ventricles of Morgagni; in front it disappeared under the anterior portion of the ventricular bands; behind one could see clearly the arc which it described; it was separated from the arytenoid region by a very small space.

The patient respired only by means of the cartilaginous portion of the larynx; had the accident happened to a child it must have proved fatal. Efforts at extraction by instruments introduced into the larynx having proved unsuccessful, an incision was made in the median line of the thyroid cartilage at the insertion of the vocal cords and the coin was removed. The patient recovered perfectly in twenty days.—*L'Abeille Médicale*, Jan. 9, 1888.

The Treatment of Otitis Media.—Cazzolino is quoted by the *Journal de Méd.* of January 15, 1888, as using the following fluid for injection in purulent otitis media:

Aquæ destill.	℥ 25.
Glycerin.	℥ 12½.
Iodid. pur.	grs. 5¼.
Potass. iodid.	grs. 30.
Acid. carbolic.	grs. 15.

Which may be diluted if its application be painful. Three injections of this fluid, when warmed, were given daily, with good results.

Fecal Tumor of the Rectum, obscuring Diagnosis.—The *Medical Press and Circular* of January 18, 1888, reports the case of a woman suffering from great pain in the abdomen and toward the back, resembling in many points a fibroid tumor of the uterus. She was constipated habitually for the previous four months, and, as a consequence, she suffered periodically from diarrhœa, but she always felt as if the rectum was not sufficiently emptied of its contents. Examination through the vagina revealed a hard globular tumor at the posterior part, but it was evident that the rectum was the seat of it. On passing the finger into the latter place a lump could be plainly felt firmly attached to the posterior wall, hard and immovable. At one point fluctuation seemed to be

present, but all attempts to dislodge it were fruitless. Cancer of the rectum could not be entertained as the most usual symptoms were absent. Suspecting a fecal collection enemas of glycerine were ordered for a week, and at the end of that period the tumor was easily broken down and removed.

Creolin, a New Antiseptic.—The Vienna correspondent of the *British Medical Journal* of January 21, 1888, writes that Neudörfer has used this antiseptic in military surgery with good results. It is a sort of tar which is obtained from the English pit coals by dry distillation, and from which the poisonous hydrocarbons have been eliminated. The chemical constitution is not yet established, but owing to its characteristic qualities it can be very easily reecognized by the practitioner. It is derived from the aromatic class of hydrocarbons, and it is closely related to creasote, carbolic acid, resorcin, hydrochinon, etc. The very first results which Dr. Neudörfer had obtained with this drug were very favorable, and he had for this reason at last abandoned all the other antiseptics and used only creolin. The first success he had obtained with it was in the case of a girl, aged seven, who suffered from *erysipelas bullosum migrans faciei*. The skin of the nose, the upper lip, and over both zygomatic arches was greatly stretched and much reddened; some pustules were also present. The lower eyelids were œdematous, the frequency of the pulse and the temperature were increased, and the patient also suffered from headache. Dr. Neudörfer said to the relatives that the erysipelas would spread over the forehead and ears, and that it would disappear in from seven to ten days. He ordered a two per cent. solution of hydrocarbonate of sodium with syrupus simplex, and directed the erysipelatous parts to be brushed thrice a day with undiluted creolin. The erysipelas did not advance; the pustules dried up; the infiltration of the skin disappeared, and the patient ceased to complain of pain. The symptoms of fever also disappeared, and the erysipelas was cured in two days and a half. Dr. Neudörfer has, since that time, tried creolin in two other cases of erysipelas with like success. In former times he used always to treat severe cases of erysipelas successfully with subcutaneous injections of carbolic acid, and he had, therefore, no reason to resort to the method of Krascke. Since he had tried creolin, however, he no longer used subcutaneous injections of carbolic acid, which had recently been again recommended by Fehleisen. The second case which had been antiseptically treated with creolin was that of a butcher, aged twenty-seven, who had cut the last phalanx of his left middle finger and the terminal front of his ring finger. After treatment with a two per cent. solution of creolin and the application of creolin gauze, the wound healed, in eight days, without suppuration or swelling. In the third case, in which a tumor in the region of the lower jaw was removed from a woman aged thirty, creolin was used during the operation and afterward as a dressing, two silk sutures closed the wound, and no drainage tube was put in. On the third day the sutures were removed; the wound was already closed, and the dressing could also be removed. The author has since used creolin in several minor operations, both in the polyclinic and in private practice, and has always observed that it relieved pain, checked the hemorrhage, and limited suppuration. At first he used a two per cent. solution, but he has now found that creolin is efficient in a one-half per cent. solution. Dr. Neudörfer prepares a fresh solution each time by adding two drops of creolin to 6 ounces of water. He uses only ungreased gauze, which, being folded from ten to twelve times, is wrung out of the milky solution and applied to the wound, which is afterward covered with several layers of dry gauze. The dressing may be left until healing has taken place. This dressing is very convenient, both for the physician and the patient, and it is also very cheap. The surgeon's wards, the patient's skin, and the instruments, can be disinfected with a two per cent. solution of creolin. For country practice, as well as for use in war, creolin is, in his opinion, the most trustworthy and convenient, as well as the cheapest and most harmless antiseptic.

A Lozenge, for Use in Phthisis.—Durand prescribes

Iodoform	gr. ¼.
Tannin	gr. 4.
Ext. caffeine	q. s.

To be made into a confection which may be taken at meals. He has found it of service in the iodoform treatment of phthisis.—*Journ. de Méd.*, January 15, 1888.

Iodine in Ascites.—Dr. Rivadeneyra, writing in *La Correspondencia Médica* on ascites due not to lesions of the heart, kidneys, or liver, but to the general condition of malarial poisoning, speaks highly of the success of iodine applications. He applies the tincture to the surface of the abdomen in strips or fringes, leaving a breadth of clear skin between each. The untouched parts are similarly painted when the iodine has caused the skin to begin to peel off. In cases where the ascites is very considerable, paracentesis is first performed, and the iodine applications commenced a few hours afterward. —*Lancet*, January 28, 1888.

The Treatment of Furuncle and Carbuncle by Spraying with Carbolic Acid.—Verneuil, at a recent meeting of the Paris Academy of Medicine, read a paper on this subject, whose conclusions were as follows: Furuncle and carbuncle (or anthrax) are but different manifestations of the same infection, to be treated on identical principles. Treatment should be surgical and topical; the use of proper topical remedies will greatly lessen the need for surgical intervention. Carbolic acid spray is a means of topical treatment, antiseptic and anæsthetic, and indicated in these affections.—*L'Union Médicale*, January 19, 1888.

Pancreatic Cyst; Laparotomy; Recovery.—At a recent meeting of the "Verein der Aerzte in Steiermark," Prof. Wölfler showed a girl in whom an incision of a cyst of the pancreas which was covered by the stomach was successfully performed. A longitudinal incision reaching from the xiphoid process to the navel was made; the stomach which lay before the tumor had to be lifted, and the transverse mesocolon was split. After the puncture of the tumor a rather large quantity of liquid escaped, which, on chemical examination by Prof. Taksch, proved to contain ferments, hence the diagnosis was thus confirmed. It was found impossible to extirpate the cyst; it was, therefore, filled with antiseptic substances, and sutured to the abdominal walls. The patient's life was

for a long time in danger, fever supervened as the margins of the cyst became gangrenous. She is now quite healthy, and a scar of the length of the section which had been made is to be seen in the middle of the abdomen. This was the first case in which a pancreatic cyst was diagnosticated in, and removed from, a woman. —*Medical Press*, January 25, 1888.

Angioma of the Epiglottis.—In the *Revista de Ciencias Medicas*, Dr. C. M. Desvernine reports an example of pedunculated angioma of the epiglottis. The patient was a man, aged fifty-three, of robust constitution, who for two months before he came under notice had suffered from occasional slight bleeding from the throat. On November 14th, he lost a large amount of blood, and the hemorrhage only ceased on syncope supervening. Laryngoscopic examination showed an ovoid tumor of lobulated appearance and dark blue color, and measuring ¾ of an inch in length by ½ in breadth, springing from the laryngeal surface of the epiglottis to the left of the middle line, about midway between the base and the apex. The tumor was attached by a short pedicle, and there was no infiltration of the tissues around its root. On November 27th, the pharynx and larynx having first been anæsthetized with a concentrated solution of cocaine, the tumor was removed with the galvano-caustic snare. The only trace of the operation was a small eschar which came away a few days later, leaving the site of the tumor completely healed. Microscopic examination showed that it was an angioma enclosed in a fibrous capsule.—*British Medical Journal*, January 21, 1888.

The Treatment of Uræmia.—Rolland has found the following prescription useful:

Ext. jaborandi (alcohol.),	
Ext. scillæ,	
Resin. jalap.,	
Resin. scammon. . . .	āā gr. ¾.

In pill form.

Four or five pills in twenty-four hours, with an exclusively milk diet, yielded good results.—*Journ. de Méd.*, January 15, 1888.

An Unusual Cause of Death after Laparotomy. — At a recent meeting of the Berlin Obstetrical Society, Olshausen reported several cases of laparotomy, in which the intestines were necessarily removed from the abdomen during the operation. The patients in question had been taken with symptoms of collapse a few days after the operation with symptoms of strangulation. Death occurred five or ten days after operation. Olshausen explained the fatal result through paralysis of the intestine and consequent absorption of poisonous feces. The intestinal paralysis is produced by the disturbances in circulation occurring in the intestine when removed temporarily from the abdomen, it is dependent on venous hyperæmia and extravasation.—*Centralblatt für Gynäkologie*, January 7, 1888.

Stone in the Stomach.—Concretions, or stones, are not often found in the human stomach, though the bezoar of the abomasum and intestines of ruminants is well known, and in olden days was very highly esteemed as a remedy against poisons and infectious diseases, being even worn as a charm. Human intestinal agglomerates are occasionally found in oatmeal-eating districts, and have sometimes been dignified by the name of "avenoliths." An enterolith was found by Laugier in a human subject, the nucleus of which was formed by a piece of liquorice root. True gasteroliths are, however, occasionally found in human stomachs; thus Schönborn was able to collect seven such cases, all of which appeared to have formed round a nucleus of hair; one of these weighed two kilogrammes. Quite recently a Dutch physician, Dr. H. A. Kooyker, has described a case of true gastric concretion weighing 885 grammes, in which there was no nucleus at all. The patient was a middle-aged man, who was so averse to examination and manipulation of all kinds that it was very difficult to form a diagnosis of his disease. He occasionally vomited blood, and gradually became more and more emaciated. A tumor was felt in the epigastrium, but its nature was not made out until the post-mortem examination revealed a stone measuring eighteen by eight centimetres nearly filling the cavity of the stomach. There was also a smaller stone situated at the pyloric extremity. These stones were of a brownish color, and the large one contained several cavities. It had an offensive smell like that of feces. A number of vegetable cells were found in it, but it was devoid of concentric or other structure. It does not seem to have been fully analyzed.—*Lancet*, January 28, 1888.

A Poisonous Ptomaine in Expired Air.—At a recent meeting of the French Academy of Sciences, Brown-Séquard and D'Arsonval reported experiments which confirm their previous studies, showing that by condensing the vapor of air expired by human beings, a liquid is obtained containing a poisonous ptomaine, which produces, when injected into the bodies of animals, symptoms of septic intoxication. When exposed to a temperature of 212° F. this fluid increased in virulence, showing that bacteria are not its potent factor. Post-mortem examination of animals poisoned by this substance showed extensive disorganization of the blood.—*Gazette Hebdomadaire*, January 20, 1888.

Lithium, in Effervescing Water.—The following powder, in a wine glass of common soda, is a convenient form of administering lithium:

Lithii carbonic.	gr. 38.
Sacchar. albi.	℥ 12½.

From 15 to 20 grains of the powder is a dose.—*Therapeutische Monatshefte*, January, 1888.

Pernicious Anæmia and the Bothriocephalus Latus.—Dr. Chapirow, a Russian physician, narrates of a lad suffering from a grave form of anæmia with febrile symptoms, extravasations of blood from the mucous surfaces and beneath the skin, etc., without any visceral disease to account for his condition. On examining the blood under the microscope the red corpuscles were found to be six times less numerous than in health, a veritable *oligocythemia rubra*. The patient's stools contained an abundance of ova. After the successful administration of a vermifuge the condition of the patient rapidly improved, and in a very short time the anæmia and its collateral symptoms disappeared.—*Medical Press*, January 25, 1888.

The Treatment of Diphtheritic Angina by Carbolized Douches.—ROULIN, in the *Journal de Méd.* of January 22, 1888, reports that he has treated 79 cases of diphtheria by douches of

Phenol sodique . . .	3 tablespoonfuls.
Water	1 quart.

without a death.

He regards the treatment as most successful in croup also. The douche was given by pressure upon a rubber bag, filled with fluid, resembling a Politzer's bag; the child was seated upon the side of the bed and a napkin put about its throat.

Intra-peritoneal Rupture of the Bladder; Laparotomy; Recovery.—WALSHAM, of London, reports the following case in the *British Medical Journal* of January 28, 1888.

C. H., aged twenty-two, was admitted March 1, 1887, into St. Bartholomew's Hospital, under the care of Mr. Walsham. He had been drinking the night before, and in a fight was butted by his opponent in the abdomen, his bladder being full at the time. He passed a night of great agony, and was brought in a cab to the hospital the following morning, but he was then suffering very little shock, and walked into the surgery with the assistance of two friends. He complained of pain in the lower part of the abdomen, and of having been unable to pass any urine since the blow, although his bladder was uncomfortably full at the time. The perineum was natural, and there was no history of stricture. On passing a catheter no urine flowed, although the point was ascertained to be in the bladder by the finger in the rectum. On depressing the handle the catheter was felt to free itself with a jerk, and its point could be then felt more plainly than natural through the abdominal walls. Bloody urine now escaped, the flow varying with respiration. About twelve hours after the injury Mr. Walsham opened the abdomen, and having discovered an intraperitoneal rent in the posterior wall of the bladder, sewed it up with nine Lembert sutures. The sutures were passed through the muscular and peritoneal coats only, and one was placed above and below the upper and lower angles of the wound respectively. The bladder having been forcibly injected with eight ounces of boric acid solution and found watertight, the peritoneum was irrigated with about two gallons of warm boric acid solution, and the abdominal wound closed as in ovariotomy. A catheter was left in the bladder for two hours, and the patient subsequently reminded to pass his urine every four hours. There was little shock, and the patient recovered. Daily notes were given at length. The author remarked that there had now been seventeen cases in which abdominal section had been performed for rupture of the bladder, three extraperitoneal and fourteen intraperitoneal. Of the three extraperitoneal cases two died and one recovered. In the successful case the wound in the bladder was secured to the abdominal wall but not sutured. In the fatal cases death was due to shock. The rent in one was found securely sutured at the post-mortem examination; in the other the rupture had not been discovered on opening the abdomen. Of the fourteen intraperitoneal ruptures the rent in the bladder was sutured in eleven, and in three a drainage tube was placed in the wound but no sutures employed. Of these three one recovered and two died, death being due to peritonitis and suppression of urine respectively. Of the eleven cases where the rent in the bladder was secured by sutures five recovered and six died, death being due in three cases to peritonitis, in two probably to shock, and in one to hemorrhage from a perineal incision employed for exploration. In the three cases of peritonitis the sutures had given way in one, and a leakage had occurred in the lower part of the wound in the other two. In the five successful cases Lembert sutures were employed, and the peritoneum was washed out, and in only one was a drainage tube used. The author discussed: 1, the advisability of early operation; 2, the importance of using a suture which will not become softened too soon, and of ascertaining before closing the abdominal wound that there is no leakage from the bladder; 3, the cleansing of the peritoneal cavity; 4, the inadvisability of a preliminary incision in the perineum, or of a subsequent incision in that region for the purpose of drain; and, 5, the question of tying in a catheter after the operation. A table of the seventeen cases was given, sixteen of which are in Sir William MacCormac's table appended to his work, *On Abdominal Section*.

The Local Treatment of Eczema.—BROCQ, in the *Revue Clin. et de Thér.* of January 19, 1888, adds to the formulæ he has already published the following:

Salicylic acid may be prescribed as follows:

Acid. salicylic.	gr. 15.
Tinct. benzoin.	℥ 30.
Vaselin.	ʒ 12½.

Acetate of lead, as follows:

Liquor. plumbi subacet. dilut. . .	ʒ 1.
Vaselin.	gr. 75.
Lanolin.	ʒ 10.

Vidal has obtained good results by the simple lead plaster of the Pharmacopœia, which he combines as follows:

Emplastr. plumbi	parts 60.
Ceræ flavæ	parts 25.
Ol. olivæ	parts 40.
Dextrin.	parts 2.
Aquæ	q. s.

Cod-liver oil plaster may be made after the following:

Empl. plumbi	parts 60
Ceræ flavæ	parts 25.
Ol. morrhuæ	parts 35.
Dextrin.	parts 2.
Aquæ	q. s.

Each of these combinations is to be thoroughly mixed, and spread upon suitable material.

Carl Braun's Method of Performing Hysterectomy.—In a recent number of the *Wiener Medizinische Wochenschrift*, Professor Charles Braun gives an account of thirty-eight cases of hysterectomy for fibroids, performed in the General Hospital, with only six deaths, that is to say, a mortality percentage of 15.5. The results which he had thus obtained were 2 per cent. behind those of Hegar, Kaltenbach, Bantock, and Keith, and about 16 per cent better than the results obtained by the Berlin

gynecologists. Professor Charles Braun is strongly in favor of the extraperitoneal treatment of the stump, as both the cases in which it was treated intraperitoneally ended fatally. According to him, the following are the indications for hysteromyomotomy: 1. Attacks of pain during menstruation or in the intervals between the periods, which recur frequently and render the patient unfit for work of any kind. 2. Functional disturbances from pressure on the neighboring organs (bladder, rectum, kidneys, stomach, or lungs) involving risk to life. 3. Severe metrorrhagia, in which a cure cannot be obtained by any less radical procedure. Instead of the aseptic sponges he in most of his cases uses mull gauze which has been for twenty-four hours before the operation boiled in a 1 per cent. solution of sublimate, and which is afterward washed in clear water. Immediately before and during the operation the gauze is wrung out of a hot solution of thymol (1 in 1000), and used for stopping the bleeding from the peritoneal surfaces after ligature of the bloodvessels. A solution of sublimate or carbolic acid is never brought into contact with the peritoneum. After the tumor has been brought forward the abdominal wound is temporarily closed by means of hooked forceps. The peritoneum of the abdominal wound is sutured above and below the stump, and the latter is fixed to the peritoneum of the abdominal wound by means of a mattress suture. Both the oviducts and the ovaries are separately ligatured with silk threads. Only after the closure of the abdominal wound by means of silk button sutures the tumor is removed, the stump being touched with the actual cautery and covered with benzoate of sodium. The extraperitoneal treatment of the stump in cases of hysteromyomotomy is specially advantageous when the myomata are situated in the wall of the body and the fundus of the uterus, but less so in those myomata which are situated between the walls of the cervix, the lips of the os, and the broad ligaments.—*British Medical Journal*, January 28, 1888.

A Paste for the Treatment of Pemphigus.—Unna, in *Monatshefte für Praktische Dermatologie*, No. 2, 1888, prescribes the following:

℞.—Ol. lini,
Aq. calcis,
Zinc. oxidat.,
Cretæ . . . . . āā equal parts.

M. f. pasta.
Sig. For external use.

Nephralgia Simulating Renal Colic.—Malécot, in a recent number of *La France Médicale*, combats the idea that nephralgia occurs frequently without the passage of renal calculi, although of small size. He has observed cases frequently where pains much less severe than those called renal colic were followed by the passage of gravel, especially in the gouty. He believes that small particles of uric acid may accumulate in the pelvis of the kidney, and passing at considerable intervals produce the pains of nephralgia. He believes that greater care in diagnosis would confirm his views.

A Study on the Etiology of Phthisis.—R. W. Philip, of Edinburgh, concludes from a series of experiments upon the sputum of phthisis that (1) in view of the work of Koch, it is impossible to avoid admitting that a causal relationship exists between the tubercle bacillus and the phthisical process. 2. The mere predication of this relationship is not sufficient in explanation of the clinical facts and the generally fatal termination of such cases. 3. The usually received explanations of the *modus moriendi* in phthisis are insufficient. 4. It appears probable that the lethal influence of the bacillus is due to the production thereby of certain poisonous products. 5. Clinical and experimental evidence appears to indicate that the morbid secretions from the respiratory surfaces afford a good medium for the growth of the tubercle bacillus, and, presumably, for the elaboration of such products. 6. Such a product is separable from the carefully selected and prepared sputum. 7. This product is possessed of well-marked physiological properties, being eminently toxic to frogs, mice, and other animals. 8. The toxic properties of the product are, speaking generally, depressant. 9. More particularly they include a marked depressant influence on the heart. 10. This depressant influence seems to be exerted through the medium of the cardio-inhibitory mechanism. 11. The toxic action of the product is more or less completely opposed by atropine. 12. The amount of the product which may be separated appears to bear a distinct relation to the abundance of the bacillar elements present. 13. Absorption of the poisonous product most probably occurs by way of the lymphatic circulation.—*British Medical Journal*, January 28, 1888.

Tertiary Syphilitic Ulceration of the Penis.—Bousquet, in the *Revue Gén. de Clin. et de Thér.* of January 19, 1888, states the following conclusions: Specific ulceration of the penis is of three distinct forms: gummæ, ulcers, and vegetations. The diagnosis of these lesions is sometimes very difficult, and the patient's statements regarding his antecedents are not to be depended upon.

The treatment by mercury and potassium iodide combined is the best diagnostic test. In a patient older than forty, who has ulcerations upon his penis, surgical procedures should not be employed without a trial of medication, regardless of the patient's statements.

The Antiseptic Treatment of Phthisis.—Spencer, in reporting a case of pulmonary tuberculosis, successfully treated by iodoform, concludes that in our treatment and general management of these cases, it is our aim to promote or bring about healing of the damaged lung tissue, and this by means of fibroid substitution. In order to attain this end, we must secure the same conditions and adopt similar measures, if we can by any means compass it, to those we find successful in dealing with suppurations, ulcerations, and the like lesions, in parts exposed to view. To secure these conditions, we should adopt measures for supplying adequate nutrition—that is, adequate anabolism of tissue and the storing of energy—in the body generally, and in the damaged part in particular. We should deal with pyrexia on its own account, as a general and constitutional state, apart from the local suppuration or ulceration (as by quinine). We should bring the lesion under the influence of antiseptic remedies, both by internal medication (as by iodoform), and by external applications (as by inhalations of eucalyptol); and the application and influence of the antiseptic should be complete, continuous, and prolonged.—*British Medical Journal*, January 28, 1888.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, FEBRUARY 25, 1888.

RESPIRATORY THERAPEUTICS.

FOR various reasons the study of respiratory therapeutics has received but little attention from American physicians. During the last few months several investigators have taken up the subject, but they have devoted their efforts almost exclusively to the pneumatic cabinet and its limited application. While it is evident that we cannot command all the apparatus at the disposal of our continental colleagues, we believe that much can be done with simpler means. Quite recently (*Zeitschrift für klin. Med.*, 13 Bd. 2, 3, and 4 Heft.), SCHREIBER has proposed some additions to the therapeutic armamentarium which we believe to be of real value, and think that by calling attention to them we can, perhaps, excite a trial of them by some of the investigators now endeavoring to solve the clinical problems involved.

These improvements consist in the use of a compressor and an elastic corset. The former is made of two plates, of a shape and size to fit the thorax in front and behind, connected by arms which allow of their mutual distance being increased or diminished, and the pressure they exert graduated in that way. The corset is much like an ordinary one, but fastened in front by a strong elastic band by means of which the pressure may be graduated circularly in any level of the thorax.

The value of these instruments can be understood by considering the objections long urged against the use of local treatment in thoracic disease; objections shown by Schreiber in some new experiments to be well founded, but capable of more or less complete suspension by the use of his inventions.

It can be demonstrated that in the ordinary application of medicated vapors and compressed or rarefied air, the diseased parts of the lungs are less exposed than the sound parts, or uninfluenced by the therapeutic attempt. By the use of properly applied compression, however, Schreiber claims that the normal parts of the lung can be entirely set at rest, and that, when this happens, the diseased part becomes at once capable of being acted upon by the medication or differentiation. As in all local treatment, thoroughness of application is of the utmost importance, and the longest possible contact of the remedy with the diseased site must be attained. Not less important is the proper selection of the remedy to be applied, and in estimating the results it must be remembered that no more should be expected of local treatment in the hands of the physician than is warranted by the common experience of surgery. Schreiber claims that in cases of atelectasis and insufficient expansion of the lungs following pleural exudates, severe acute pneumonia, adhesions, and pneumothorax, the value of the compressor can be easily demonstrated.

In catarrh, or ulceration, abscess, gangrene, and tuberculosis, less is to be looked for, and disappointment not so much to be feared from the mechanical as from the pharmacological factors in the method. Schreiber's arguments in favor of circular compression in chronic emphysema and the secondary atelectasis following long-continued coughing in that disease, are plausible, and, according to him, the new methods seem much more likely than the older ones to remove the anatomical basis of the emphysema.

It is evident that the *post hoc* arguments of single observers cannot lead to a definite advance in respiratory therapeutics. Experiments on animals are excluded by the differences in the form of the animal and human thorax. With the pneumatic cabinet and any ordinary atomizer, and such compressors and corsets as are mentioned above, it would be easy to ascertain the value of the improved therapy, and, premising a proper adaptation of medication and method to individual cases, we believe it fruitful of good results.

JOSEF HOFMANN'S HEALTH.

JOSEF HOFMANN, the musical prodigy, is an intelligent-looking boy, ten and a half years of age. He

now weighs sixty-three pounds. When he left Europe for this country, he weighed fifty-six pounds. He began to study music at the age of about five years. The *technique* of the piano was to him unusually easy, and his musical memory was remarkable and did not require much special cultivation. His muscles are well developed for a boy of his age, especially those of the arms and hands. His hands, though of ordinary size, are very thick and strong. He presents absolutely no evidence of any organic, nervous, or other trouble. He eats and sleeps well, and takes four meals a day. His movements and demeanor, when subjected to medical examination, are quick and nervous. He says, himself, that he is fond of playing the piano, but is tired of playing in public. According to his father's statement he now practises very little, and it is not often necessary for him to rehearse before performing in concert. His variations and improvisations on given themes are spontaneous, and the skill which he possesses in this regard is the result simply of what he has learned from hearing music. He has never made a serious study of harmony and composition.

His work at concerts has lately been very considerable, almost excessive; but it is understood that the programmes have been made by his father and his father's musical agent, and that he has often, in Europe, done as much. At his last concert, he played a long concerto by Beethoven, with orchestra, a polonoise with orchestra, a duet with harp, an improvisation, and four solos. He says that he was very much fatigued after this concert, which occurred in the evening, that he urinated freely after each piece, and wet his clothing while performing. His urine has been frequently examined, and has always been found normal. A specimen passed in the presence of physicians in consultation in his case on Monday last, had a specific gravity of 1024½, was acid, contained no albumen, or sugar, presented a deposit of a faint cloud of mucus on standing for eighteen hours, and had 10¼ grains of urea per ounce. He does not and never has suffered from enuresis. He complains that he is much fatigued by travelling. He plays with toys, etc., like other boys of his age, but much of his time is taken up by a certain amount of work which he has to do in public. It is evident that his concerts have become irksome to him, although his intense love of music is undiminished.

As far as it is possible to judge at present from a physical examination, his work in this country has not impaired his general health. Assuming the accuracy of the statements with regard to his incontinence of urine during public performances, this is the only indication of any excessive nervous strain. The stains on his clothing are very slight, although it is said that his mother has observed them for several weeks. It is positively stated that he does not suffer from incontinence when playing or practising at home.

The general education of the boy has been somewhat neglected, but he speaks and writes Polish, which is his native language, German, and French. He is evidently intelligent, and has considerable mechanical talent. He is also fond of drawing and painting. As regards the future, and the prospects of the full and mature development of the great musical genius which Josef Hofmann undoubtedly possesses, prudence dictates that he should avoid any possibility of overwork.

Judging from the existing conditions and indications, there seems to be no sufficient reason why his public performances should not be continued in moderation; but excessive physical fatigue, as in travelling, should be guarded against, and the part which the boy bears in his concerts should certainly be curtailed. He ought not to be called upon to play at any concert more than one serious composition for the piano, or orchestra, one short solo, and one improvisation; and he should have ample time for rest between his public performances.

It should be borne in mind, also, that Hofmann is no ordinary child. His performances are not merely mechanical displays of technical skill; but they involve a condition of nervous exaltation which is evident enough from the poetic and artistic feeling with which he interprets musical compositions of the highest order.

FATAL POISONING BY QUININE.

Death so rarely occurs as the result of the ingestion of this drug in large amount that the paper of Husemann, in the *Therapeutische Monatshefte* for January, 1888, is of great interest. A number of the text-books on materia medica and therapeutics state that no deaths are reported, and it has been generally supposed that the reason for this was the fact that just so soon as the excess of quinine reached the small intestine it was precipitated, and so discharged with the feces. It is evident, too, that the irritant effects of large amounts of quinine are liable to pro-

duce not only vomiting but purging, both of which actions would aid in the recovery of the patient.

Death is, of course, readily produced by quinine, if given hypodermatically, and the early symptoms of the poisoning are so familiar to every one as to need no mention here. It will be remembered, too, that where death is produced great meningeal and cerebral congestion is always present, with, in some instances, hemorrhages into the middle ear, the blood dark and readily coagulable, and preceding death, in rare cases, a peculiar condition is developed in which the animal beats its head constantly on the floor as it lies on its side.

The three cases themselves, as recorded by Husemann, are taken from a paper by Kinner, of St. Louis, and but two of them were fatal. The salt was the sulphate, and was prepared by William Warner & Co., of Philadelphia. In the first case a child of three and a third years swallowed about twenty-five two-grain sugar-coated pills, shortly afterward complained of headache, vomited, passed into a condition of stupor, and this was followed by death in about one and a half hours after the taking of the drug. In the second case a girl two years old took from eight to ten two-grain pills, and was given an emetic, but died, in about two and a half hours, with rigors and a convulsion. In the third case a somewhat corpulent woman of sixty years, with intermittent fever, took upward of one hundred grains, and was found by Kinner with a pale, cool skin bedewed with sweat, and suffering from dyspnœa. The pulse was small and feeble. Coffee and whiskey were given freely, and recovery took place, although severe ear-ache followed the next day.

The treatment of such a condition resolves itself into the treating of circulatory disturbances, which are always great, owing to the depressing effect of quinine on the heart, by the use of cardiac and also of respiratory stimulants; the use of tannic acid to form a tannate, to be followed by a mild purge, and the maintenance of bodily heat.

Dr. Edward Jackson has been elected Professor of Diseases of the Eye at the Philadelphia Polyclinic.

At Waldeck, Germany, a law has been adopted forbidding the granting of a marriage license to any person who has become addicted to alcohol.

Professor Kussmaul, after a long and brilliant career, has retired from the University of Strassburg, where he has held the Directorship of the Klinik for Internal Medicine. Professor Naunyn, of Königsberg, has been invited to succeed him.

At a recent meeting of the Clinical Society of New York, Dr. F. H. Hartley gave the history of a case of supernumerary arm, in a boy about ten years of age. The third arm is on the right side of the trunk, and is quite completely developed, but it has no scapula.

A wooden case, containing a complete outfit of surgical instruments has recently been discovered at Pompeii. Many of the implements are said to bear a very close resemblance to those used at the present day.

In Corea, according to the *Missionary Review*, an American lady, Mrs. Dr. Ellis, is the physician to the Queen, and has apartments in the royal palace. Her salary amounts to $18.000 per annum.

Dr. Lilian Horton, a graduate of the Chicago Woman's College, has just sailed from San Francisco to take the position of Assistant Physician to the Queen and Physician in charge of the Hospital for Women.

The Medical Jurisprudence Society of Philadelphia has elected the following officers for the year 1888:

President.—Charles K. Mills, M.D.

Vice-Presidents.—John A. Clarke, Esq., and Henry Leffmann, M.D.

Secretary.—F. X. Dercum, M.D.

Treasurer.—Paschal Coggins, Esq.

Recorder.—G. Milton Bradfield, M.D.

SOCIETY PROCEEDINGS.

THE PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, February 6, 1888.

The President, D. Hayes Agnew, M.D., in the Chair.

Dr. W. W. Keen reported a case of

OMPHALECTOMY FOR STRANGULATED UMBILICAL HERNIA.

(See page 205.)

Dr. Hunt asked if Dr. Keen had looked up the mortality following this operation. He had not seen many cases, but his personal experience is that the prognosis in operations for strangulated umbilical hernia is bad.

Dr. Gross understood that Dr. Keen excised the opening simply for the reason that he could not bring the edges together.

Dr. Keen said the operation was done purposely. He had decided that if he did operate this would be the operation which he should perform.

Dr. Gross asked if he would then prefer this operation to that of freshening the edges and bringing them together?

Dr. Keen stated that he should prefer it.

Dr. Gross remarked that the operation for strangulated umbilical hernia by freshening the edges and bringing them together is not an uncommon one. He had references to a good many cases, but they have not a very good prognostic import. He recently had a letter from a physician who, in a case of strangulated umbilical hernia in a woman, had cut down, reduced the hernia, and sutured the ring. The woman died, and he was subjected to the annoyance of a suit for malpractice. He wrote to him for his opinion. He told him that he had pursued the proper course. It so happened that at the same time he saw in a foreign journal the report of three cases of the same operation, which he sent to him, and he was acquitted.

In operating in cases of strangulated umbilical hernia, he saw no reason for removing the opening or excising the median line, if the same thing can be accomplished by freshening the edges of the ring. On the other hand, he did not know that there are any objections to the procedure.

Dr. J. M. Barton recalled three cases, two of which recovered and one died. In one case, he succeeded in freshening the edges and bringing the wound together. In both of the other cases this was utterly impossible, the abdominal walls being very fat and from two to three inches in thickness, within this fat the hernial sac had burrowed laterally, so that though its contents would fill a twelve ounce graduate, it did not elevate the skin. The description of the contents which had been given by Dr. Keen would apply perfectly to his cases; a mass of omentum folded up like the leaves of a rose, and in the centre of the mass a small knuckle of intestine. In another case he freshened the edges, but he could not pass the stitches on account of the depth of the wound and the portions of omentum in the way. He broke a needle or two before giving it up, and then closed the wound by bringing some of the omentum over the opening and fastening it; this case proved fatal. The third case occurred in the Jefferson Medical College Hospital. He operated and the woman was relieved, but in a few months she again had strangulation, and was operated on by one of his colleagues. She recovered from the second operation also.

If in the future he should have difficulty in bringing the edges of the hernial opening in apposition, he should adopt the method brought to their notice by Dr. Keen. If it were possible in performing the operation to make the section through all the tissues except the peritoneum, and permit this to fold, he thought it would slightly lessen the risks.

Dr. W. W. Keen said that an examination of the literature verifies the assertion that the rate of mortality is very high. He thought that for this very reason omphalectomy is rather to be chosen on account of the harmlessness of abdominal section at the present day; and although here complicated by hernia, yet at the same time, unless the condition of the intestine be very bad, it seemed to him that the rate of mortality should not be much higher than in ordinary laparotomy. In almost all cases of laparotomy there is some complication which adds to the dangers of the section itself. He quite agreed with the statement of Dr. Musser, that it would have simply been a mechanical impossibility to freshen the edges of the opening and bring them together. As in the case alluded to by Dr. Barton, he found during the operation that the thickening felt for two fingers' breadth around the umbilicus, was due to enlargement of the cyst in the wall of the abdomen.

Another reason for choosing this operation in cases of hernia, is to prevent the return of the hernia. In one of the three cases reported by Dr. Barton, the hernia returned. If omphalectomy is done, the return of the hernia is rendered impossible. He had a firm belief that the mortality will be less than in ordinary herniotomy followed by excision or ligature of the sac. Cutting operations limited to the hernia itself, without opening the peritoneal cavity, without any attempt at removal of the umbilical opening, have already been done in several cases with greater or less success.

OSTEOGENIC POWER OF BONE CELLS.

Dr. Charles B. Nancrede, in presenting a specimen, remarked that a great deal of attention has of late been directed to the question of the osteogenic power of the medullary cells. He did not wish to detract from the value of the observations of Dr. Macewen, but he should like to claim for America the priority in the recognition of the osteogenic power of the bone cells. So far back as 1871, it was so well known, that Eve relates in his *Rare Surgical Cases*, that non-professionals on the frontier posts were accustomed to perforate the external table of the skull with an awl in many places in cases of scalping. Over twenty years ago he saw Prof. Agnew resort to the same procedure in case of an injury to the head. The operation succeeded, but the patient, however, died from some encephalic complication.

In 1883, when he was preparing the section on Head Injuries, for the *International Encyclopædia of Surgery*, he called attention to this matter, and mentioned this case. Six months later a patient was brought to the Episcopal Hospital with his arm injured by a calendering machine, in which there are two rollers, one hot and the other cold. The hot roller was applied to the posterior surface of the arm producing a slough of the greater portion of the skin of the forearm, including the muscles and some of the tendons. These were stripped off in a dead state from two-thirds of the circumference and from two-thirds of the length of the ulna. It occurred to him that it would be a good idea to see if the formation of bone would not be facilitated in the ulna by drilling into the medullary cavity of the bone. He drilled a good many holes into the ulna, having to go at least three-sixteenths of an inch before bleeding commenced. The ulna which was secured was very substantial, and more like an uninjured ulna than if left to nature. In a few days granulations sprang up from the ulna and fused with the granulations from the soft parts, and in course of time this fragment was separated.

There are some bones in which we should avail ourselves of the osteogenic formation of the medulla, and there are some in which no such attempt should be made. There are not so many medullary cells in the inferior maxillary as there are in the diploë, so that we may take

out a portion of the skull and have the bone restored; but in the case of the lower jaw, if a piece of the outer plate is removed and then replaced, it is unlikely that the graft will be successful.

DR. KEEN said that the remarks of Dr. Nancrede, with reference to the behavior of different bones, are well illustrated by a case recently under his care. Following the practice of a number of surgeons with reference to the bones of the skull, and also with the view of closing up the canal of the inferior dental nerve in a case of resection of the inferior dental nerve for persistent neuralgia, he lately replaced the buttons of bone that he had removed. Immediately after removal they were placed in a warm solution of carbolic acid, and so preserved until replaced. For about ten days they did perfectly well; then symptoms of irritation appeared, and in four or five days became so severe that he was obliged to open the wound and remove the pieces of bone; after that the case did well. He thought that this procedure was worthy of a trial; but he would scarcely be disposed to try it again. Probably the more compact tissue of the outer layer of the lower jaw, as compared with the cranial bones, may account for the non-viability of the former.

DR. HUNT said that the great practical point to be derived from these facts in reference to bone, is that it will lead to a revival of the old practice which he had always advocated, of not interfering too much, and often making practical resections in cases of compound comminuted fracture. Let the little attached pieces of bone alone, and they may do the work of union. If they separate, take them away. Since antisepsis has become so usual, and the desire prevails to take everything supposed to be irritating away, he had seen many cases of the most beautiful results externally, so far as the healing was concerned, but nothing but an imperfect union inside, simply because much that might have been reparative was removed. That he thinks is a wrong practice.

DR. C. W. DULLES said that *apropos* of what Dr. Hunt had said, he might speak of the case of a little girl, three years old, who was run over by both wheels of a passenger car. He saw her in the middle of the night at the Presbyterian Hospital. He examined the case thoroughly, and considering the tender age of the patient, and the fact that the operation called for, if any were necessary, was amputation, and that children have better chances of recovery than adults, he decided that he would give the child the chance of recovering with her leg instead of that of dying without it. The case was afterward under the care of Dr. De Forest Willard. To make a long story short, the child never had any pain or fever, and made an uninterrupted recovery.

Shortly after this, he saw another little girl, five years of age, who had her thigh caught between a heavy piece of timber and the corner of the curbstone, producing a compound comminuted fracture just above the knee, so close that it was impossible to say whether or not the joint was implicated. In this case also he decided that it was proper to give the child a chance of living with her leg. This case was afterward under the care of Dr. C. A. McCall. There was some separation of fragments of bone, and it was several months before the child was entirely well, on account of sloughing of the soft parts, the result of the contusion. She, however, eventually recovered entirely, with some little malposition of the lower part of the leg.

He mentioned these cases partly to enforce what he considered the very sensible remark of Dr. Hunt, and because he too thinks there is a temptation, on account of the facility which antiseptic methods afford, to remove more than there is any necessity for. It would frequently be a good thing to give nature a chance to recover and let her cast off what she cannot deal with.

DR. NANCREDE said that the same rules hold good with reference to primary, secondary, and tertiary sequestra under antiseptic as under other methods of treatment. He thought that we are not in the habit of removing any more fragments than formerly. If a fragment has no connection with the soft parts it may indeed act as a foreign body, but after Macewen's experience he should be inclined, instead of removing a fragment, to take it out and cleanse it if necessary, and then replace and secure it in some way. He thought that there is no difference under the antiseptic methods as to the removal of fragments, except where it is necessary to secure drainage, and this can be usually accomplished without any serious sacrifice.

He had treated many cases of compound fracture under the antiseptic method, and had seen no difference in the method of union except that we do not have fever and other troubles.

Dr. HUNT said that he meant no attack upon antisepsis. It secures beautiful results. He would have the cases treated by antiseptic methods, but at the same time he should let the attached fragments remain to do their work.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 16, 1888.

THE PRESIDENT, A. JACOBI, M.D., IN THE CHAIR.

THE CARE OF THE PAUPER INSANE.

DR. SAMUEL SEXTON presented a resolution endorsing the bill prepared by the State Charities Aid Association regarding the care of pauper insane in State hospitals, and recommending its enactment by the Legislature. It provides that the State shall be divided into as many districts as there are State hospitals for the insane in the State; that there shall be erected on the grounds of each State asylum a sufficient number of buildings of moderate size to accommodate all the pauper insane of the district in which it is situated; that there shall be a uniform charge of all State asylums to the different counties not exceeding $1.50 *per capita*, per week; that after the completion of the buildings provided for in it it is the intent and meaning of this act that no insane shall be kept under county care within the counties embraced in it (New York, Kings, and Monroe counties are excepted from its provisions); that the State shall pay all expenses incurred beyond the rate of $1.50 *per capita* per week for the support of the pauper insane; and that the sum of $500,000 be appropriated for carrying the act into effect.

Those members of the State Charities Aid Association who are as familiar with the management of the State hospitals as they are with that of county poor-houses, find themselves obliged to acknowledge, in accordance with universal testimony, that the care furnished the insane by the State is mostly superior to that furnished by the counties. They know also that the counties do

not propose to give the same character of care to their pauper insane as that given by a State hospital, with its staff of alienist physicians always in attendance, its schools for training nurses, its larger force of attendants, its various organized systems for occupation, instruction, and amusement. This is impossible of attainment for any county at a weekly cost per capita of $1.50. The expense of new or improved county buildings, and of a larger number and higher grade of attendants, which an advanced and enlightened public opinion now demands for the care of the insane, these two treatments alone—irrespective of maintenance and medical treatment—will impose a heavier burden on the taxpayer of the county than the additional increase of his State tax required to perfect the system already established by the State.

In seconding Dr. Sexton's resolution, Dr. C. R. Agnew said that for thirty years he had been interested, with others, in the amelioration of the condition of the pauper insane in the State of New York, and that the first result of the agitation of this subject had been the establishment by the State of the admirable Willard Asylum. Later those at Binghamton and Poughkeepsie had been started. The opening of these institutions had withdrawn a considerable portion of the pauper insane from the county poor-houses. Now, however, an effort was being made to establish county asylums for the insane. The chief reasons alleged for this measure were the saving, to a considerable extent, of the cost of the transportation of insane patients, and because the cost of maintenance in the State hospitals was unnecessarily great. One of the counties undertakes to care for its insane at a cost not to exceed 97 cents per head per week, and another of $1.19. At the Willard Asylum, where the number of inmates is nearly 2000, the expenses cannot be reduced below $2.50 per head per week; but this included the best scientific care by expert physicians and specially trained nurses, the amusement and intellectual training of the patients, and their employment in the workshop and on the farm connected with the establishment. It is a fact, also, that some of the counties have tried the experiment of having their own insane asylums, and unsuccessfully. Thus, Rockland County erected one at an expense of $20,000, and it has now been abandoned. If the pauper insane are cared for by the counties they will be under the charge of the Supervisors and Superintendents of the Poor, and these men, besides knowing nothing of the proper care of the insane, are altogether too close to the taxpayers. This class of cases can, in fact, only be properly taken care of in an institution where there is a Board of Managers which is directly responsible to the State, and where everything is done under the blaze of public scrutiny; and in the State hospitals he believed that the most enlightened modern treatment of the insane was carried out in as thorough a manner as possible.

The resolution was then unanimously adopted.

Dr. H. Seibert read a paper on

Cholera Infantum and the Weather.

Under the term cholera infantum he said that he referred to all cases of acute gastro-intestinal catarrh in children under five years of age. The paper was based upon observations made during a period of ten years, from January, 1878, to January, 1888, in the children's department of the German Dispensary, and was illustrated by a large number of charts. In a similar manner, he said he had endeavored to point out the relation of fibrinous pneumonia to the weather in a paper published in the *American Journal of the Medical Sciences* in 1882. The total number of cases of acute gastro-intestinal catarrh treated at the dispensary during the ten years referred to was 8036. As was naturally to be expected, the greatest number of cases occurred during the summer months, and the fewest in the winter months. Thus, in the ten Julys there were 2443 cases, and in the ten Augusts 1524 cases; while in the ten Februarys there were only 117 cases. The monthly averages, however, were simply guides in the present inquiry, and it was not enough to take these alone. His statistics, as well as those of the Health Department, showed that the disease exists all the year round, even in the coldest weather, and that the proportionate mortality is just the same in cold as in hot weather—about one case in every four proves fatal.

It is a somewhat remarkable fact that the number of cases and deaths is always much greater in the month of July than in August. Thus, during the ten years the number of deaths reported in the city of New York in July amounted to 12,428, and those in August only to 6205. In July, 1881, when the mean temperature was 80°, the number of cases treated at the dispensary was 290; in August of the same year, when the mean temperature was 82°, the number of cases was 223; and in September, when the mean temperature was 87°, the number of cases was 137.

During the summer months it was found that the number of cases and of deaths bore no relation whatever to the rise and fall of temperature, and the same was true as regards the range of humidity; so that warm moist weather does not predispose more to the disease than warm dry weather. Dr. Seibert said that he had also made a very thorough investigation of the effect of light and heavy rainfall; but totally without result. Previous to this it had been a favorite belief with him that want of water on the upper floors of tenement-houses was a somewhat important factor in the causation of summer complaint in the city. Local rainfall also had no effect; and the same was true in regard to the velocity of the air-current. Six years ago he said he had first pointed out the necessity of careful study of details, rather than of general averages in connection with such subjects as this.

As yet it is a disputed point whether direct heat is capable of causing the disease in question, and he has made a special study of all the hot days in the ten summers (when the temperature reached 85° or higher), According to the prevalent opinion, the months containing the greatest number of hot days ought to have the greatest number of cases and of deaths; but he has found no evidence supporting this idea. Thus, in the last two weeks of June, 1880, there was a large proportion of these hot days, and in the same period of 1887 there were but few of them; yet the number of cases was just about the same in both of the fortnights mentioned. Again, in July, 1881, when there were but few hot days, there were 290 cases; while in July, 1887, which was considerably hotter, there were only 196; a ratio of 3 to 2. In July, 1884, the temperature never reached 90°, there were but three days when it went above 85°, and but eight days when it went above 80°, yet there were 266 cases; while in August of the same year, which was

a much hotter month, there were only 156 cases, or about one-third less. The difference in mortality in the city during the two months was even more marked; the number of deaths being 1109 in July, and only 633 in August. Yet this July was made up for the most part of what is usually regarded as very healthy weather; little excess of heat, frequent showery days, and many days with strong westerly breezes.

How, then, are we to account for the fact that in the warm months there are always such a large number of cases? It is evident, from the facts just pointed out, that *hot* weather is not necessary for the production of the disease. In regard to *warm* weather, however, the case is different, and the statistics collected showed that in the early part of the warm season, as soon as the minimum daily temperature reached 60°, and this continued for a few days, an increase in the number of cases of acute gastro-intestinal catarrh was noticed. Furthermore, if the minimum daily temperature remained above 60° for a number of days, say a week or more, it was noticed that the disease became epidemic; and this, no matter how high above 60° the temperature might go, whether it was 75°, 80°, or 85°. These facts were found to be true in every one of the ten years which the statistics embraced.

The reverse was noticed at the close of the warm season in October, the month of departure. During the first half of the month the minimum daily temperature usually reached 60°; but in the latter half, when colder weather set in, the end of the epidemic occurred.

An examination of every summer month, and of every day of each month during the ten years, had led him to the following conclusions:

First. Hot weather, either dry or moist, is not necessary for the epidemic appearance of acute gastro-intestinal catarrh.

Second. Warm weather, either dry or moist, showing a minimum daily temperature of not less than 60°, brings on the epidemic every year, irrespective of the maximum daily temperature.

Third. The disease loses its epidemic character as soon as the minimum daily temperature falls below 60°, as in October.

Fourth. Therefore, this disease cannot be brought about by the direct effects of high temperature upon the child's body.

Dr. Seibert then went on to say that the lowest temperature of each day is reached during the night; and it is at this time that the milk which furnishes the principal food of so many young children is brought into the city. It is often carried long distances, being jolted about, and absorbing impurities from the time it leaves the car. It is, therefore, only a question of time how far the decomposition of the milk is advanced by the time it reaches the child. It is well known that a low temperature retards decomposition, and Dr. Cyrus Edson, of the New York Health Department, had informed him that, in his experience, he had found that milk usually began to turn whenever the temperature reached 60° or higher. Chief Engineer Birdsall, of the Department of Public Works, had also informed him that he had noticed that whenever the temperature of Croton Lake rose to 60°, or above, there was a peculiar taste about the water, which was, no doubt, due to the decomposition of certain matters contained within it.

As to the point why there are always so many more cases and deaths in July than in August—the difference usually amounting to one-third—it seemed to him that it might be explained by the circumstance that it takes a few weeks, after the onset of warm weather, to arouse fully the tenement-house population of the city to the danger to which their children are exposed from this disease, and to cause them to take the necessary precautions, as regards diet, fresh air, sanitary conditions, etc., for its prevention.

DR. L. EMMETT HOLT quoted some statistics of a Liverpool physician for the five years ending with 1883. In one of these years the mortality amounted to 347 in July, and 969 in August. The average temperature of July was 58.9°, and of August 59.2°; and this would seem to confirm Dr. Seibert's statement, concerning the increase of the disease when the temperature approached 60°. In September, however, when the average temperature was only 55.9°, there were 589 deaths, which, while much less than the mortality of August, was considerably greater than that of July. Still he thought that this might, perhaps, be explained by the fact, which he himself had noticed repeatedly, that a very hot August is apt to be followed by a high mortality in September, irrespective of the degree of heat in the latter month. Very much the same ratio, as regards the different months, was observed during the other years covered by the Liverpool statistics.

Dr. Holt then went on to say that in summer there are different forms of diarrhœal disease in young children, and that he scarcely thought it advisable to class them all under one head. In the production of what is ordinarily known as "summer complaint" he believed that there are four principal factors, viz.: (1) heat; (2) feeding; (3) sanitary conditions; and (4) constitution; and that the most important of these is heat.

DR. J. LEWIS SMITH said that he quite agreed with Dr. Holt that the cases are by no means all of the same disease. He had some cases in the warmest weather in which there was an aggravation of the symptoms resulting from reduction of temperature. The child took cold, and the disease was then apt to assume a dysenteric tendency. He thought there is perhaps a fallacy in comparing summer diarrhœa with the diarrhœa met with in cold weather, as he believed the latter to be a different affection from the former. In the cooler months the causes of the trouble are usually so different that it is unjust to compare the two diseases, although the lesions may be the same. The difference between the two is as great as that between the bronchitis incident to pertussis or measles and idiopathic bronchitis.

It seemed to him also that we might be misled by the number of deaths reported. Thus many of the deaths occurring in August or September might be in children who contracted the disease in the earlier part of the summer. The mortality, as a rule, was somewhat greater in September than in May, although the temperature was usually lower in the former than in the latter month; and the reason was because many of those dying in September had been taken ill in one of the previous months. He had noticed in his own statistics the difference between the mortality in August and that in September.

It could be stated in a general way, he thought, that the disease known as summer complaint is caused by heat; but in what way the heat operates to produce

it is not as yet fully ascertained. It is evident that heat alone is not sufficient for its production, or else the disease would be found prevalent in the country as well as in the city. It must be a fact, therefore, that there are certain causes which are brought into operation by the unsanitary conditions met with in the city in hot weather. How much gaseous exhalations have to do with the causation is not determined. At all events the opinion is gaining ground among the best observers that summer diarrhœa is a microbic disease. It is well known that milk which has begun to decompose has a tendency to give rise to the affection. In Asiatic cholera the causative agency of Koch's bacillus has now been pretty generally accepted, and it is believed that this microbe is received into the mouth and acts as a source of irritation to the intestines by its actual presence, and not by causing decomposition of food. In like manner it does not seem unreasonable to suppose that microbes may act in the same way in some cases of summer complaint.

Dr. A. Caillé said that the investigations of Dr. Seibert had not only confirmed the general opinion that warm weather is an important factor in the causation of summer diarrhœa, but had also brought out a number of interesting new facts. In his opinion decomposing milk is the chief exciting cause of the trouble. While Dr. Seibert was on the whole, no doubt, right, it was his opinion that high temperatures sometimes have a pernicious effect upon the human body, and thus serve to pave the way for some agency which will give rise to summer complaint. It is a fact that children nursed at the breast or brought up upon some of the numerous infants' foods in the market, who never get cow's milk, will sometimes be attacked with serious diarrhœa if allowed to overload their stomachs in warm weather, while they will suffer but little, if at all, under the same circumstances in cold weather.

Two French physiologists made some experiments by exposing animals to a continued temperature of 104°, and the phenomena which they noticed to result from this exposure were (1) increase of nervous excitability, (2) nervous depression, and (3) convulsions, coma, and death; death resulting more speedily in a moist high temperature than in a dry one. The same results had been noticed to be produced in children when the weather was very hot. It was his opinion, therefore, that while high temperature does not directly produce diarrhœa, it does have a pernicious effect upon the system, and under these circumstances any irritating substance would be likely to give rise to diarrhœa. As regards the smaller number of cases of summer complaint, as well as deaths, in August than July, he thought that perhaps one reason for this was that a much larger number of children leave the city in August than in July, while those which remain have the advantage of the numerous fresh air excursions then provided for the poor.

The President said that there is a great difference in the cases observed. The larger number are of a simple catarrhal nature. In others, where there are serous discharges there is a tendency to collapse. In such cases after death the lesions found in the intestines may be very slight, while several of the organs of the body may be in an advanced stage of granular degeneration. He believed that great heat kills by its direct effect upon the nerves and upon the muscular system, including the tissue of the heart itself; the high temperature having the effect of coagulating the myosin of the muscles. Intense heat also has a certain influence on the surface of the body, causing an immense dilatation of the capillary bloodvessels. Insufficient nutrition, particularly of the brain, results from this, and thus collapse is brought about. These are the cases which terminate fatally, and they are liable to be met with in well-to-do families as well as among the very poor. The affection referred to constitutes true cholera infantum. The larger majority of the cases met with, however, are of gastro-intestinal catarrh. He had been much interested in the fact demonstrated by Dr. Seibert's investigations that 60° was the turning-point for this disease, and it was especially noteworthy in this connection that Dr. Edson had expressed the opinion that milk began to decompose, and Chief Engineer Birdsall the opinion that water began to be affected by decomposition also at 60°. In conclusion he made some remarks in regard to the importance of proper feeding.

NEWS ITEMS.

The Illness of the Crown Prince.—The *British Medical Journal* of February 11th states that "We learn by special telegram from San Remo that the Crown Prince's symptoms had become so urgent that tracheotomy had to be done on Thursday morning. We are pleased to say that the operation was performed with complete success. It is natural enough that some alarm should be felt by the public that this procedure should have become necessary. Our readers, however, will no doubt remember that we have more than once hinted that such a contingency was not unlikely to arise, and last week we intimated, as plainly as was possible under the circumstances, that the time was not far off when the operation would be imperatively required. It is quite inaccurate to speak of the Prince's present condition as a 'relapse;' the local symptoms have simply become rather suddenly intensified without any substantial change in their character. The possibility of such an event has been clearly foreseen all along, and it has been obvious for some months past to those acquainted with the facts of the case that tracheotomy, sooner or later, was inevitable. We are in a position to state that all these points were fully explained, a considerable time ago, to the illustrious patient himself, and to his relatives, both in Germany and in this country.

"It may be well to emphasize the fact that the necessity for surgical interference which has arisen does not in the least degree contradict the more favorable reports as to His Imperial Highness's condition and prospects which we have lately been able to give. It is still highly probable that the disease is not cancerous, but obstruction of the larynx, however 'innocent' in itself, is a complication that can only be dealt with effectively by the surgeon's knife. It should be distinctly understood that the operation, when done, as in the present instance, merely as a security against possible accidents in the future, is not only very slightly dangerous in itself, but is one of the most successful in surgery. There is no reason why a man suffering from a disease which obstructs the upper orifice of the windpipe, but does not spread to neighboring parts, should not, if tracheotomy is performed in

time, live out his full natural lease of life. If, at any subsequent period, the passage becomes clear again, the tube can be removed; if not, it may continue to be worn with comparatively little inconvenience or discomfort. With a properly constructed instrument the patient is not only free from all risk of suffocation, but is able to speak with perfect ease and distinctness, and can discharge the duties of life, and take part in most of its pleasures, without trouble to himself or distress to others."

A Four Years' Medical Course at Harvard.—From an examination of the last report of the Harvard Medical School, the *Boston Medical and Surgical Journal* of February 16, 1888, concludes that, in plain words, it appears in the first place that not one-half of those who take the fourth year course apply for the fourth year degree. Secondly, the percentage of rejection at the examinations for the fourth year degree is so large, that prudent students may well prefer to take the third year degree at the regular time, rather than to run the risk of having to fall back upon it after failing to get the fourth year degree. During the past four years, the percentage of rejection for the fourth year degree has been 35 per cent., while the percentage of rejection for the third year degree has been only 16½ per cent. Thirdly, it is evident that there have been two sorts of students in the fourth year class: one sort, the most promising men in the school; the other sort, men who need four years of study in order to obtain the third year degree. The number of examinations which the student was expected to pass at the end of the fourth year has been unreasonably large.

The experiment, as a whole, is not yet successful; and such inferences as can safely be drawn from it do not encourage the hope that a fourth year of study can soon be demanded of all candidates for the degree of Doctor of Medicine, unless, indeed, the school shall receive a special endowment to enable it to take this costly step.

Three Years' Study Obligatory in California.—At a recent meeting of the Board of Managers of the Medical Society of the State of California the following resolution was unanimously adopted:

"*Resolved*, That on and after April 1, 1891, the Board of Examiners of the Medical Society of the State of California will not grant certificates to practise medicine on diplomas issued after that date, by colleges which do not require that all candidates for graduation shall have studied medicine not less than three full years, and shall have attended not less than three full regular courses of lectures, delivered during three separate years."—*Sacramento Medical Times*, February, 1888.

The New Pasteur Institute.—The buildings (*Figaro* states) are already rising over the space of 10,000 *metres* which the Institute is to cover. Two principal pavilions will contain the laboratories, the amphitheatres, and consulting rooms. There will be no hospital, for, we are told, the Institute "is not a *maison de santé*, but a school." On each side, uniting the pavilions, will be stables, fowl-houses, kennels, and rabbit-hutches for all the animals required for the various researches, which will not be confined to rabies, but will embrace all contagious diseases. Only one department will be devoted to rabies, at the head of which will be M. Grancher, who is styled "Apostle of the Religion of which M. Pasteur is the Prophet." The second department will be devoted to *inoculations charbonneuses*, swine measles, and calf-vaccination; the director being M. Chamberland. The third will be entirely private, devoted to researches in bacteriology, under M. Dudaux; and the fourth to medical bacteriology, under M. Roux. The building is calculated to cost a million of francs, and the remainder of the funds subscribed will endow the institute, when opened next June, with something like sixty thousand francs (£1500) a year.

The Archives de Tocologie.—On January 1, 1888, this journal passed from the management of Prof. Depaul to that of Dr. Auvard, of Paris.

Fees for Expert Testimony.—The Texas Supreme Court has just decided a case of great importance, not only to the physicians of Texas, but to the entire profession. Dr. J. B. Fearns, of Garrison, sued Nacogdoches County, in a lower court, for payment for expert services as a witness in a homicide case. The amount involved was small, but Dr. Fearns deemed the principle of so great importance that he submitted to the necessary legal expenses to test it. The lower court decided against Dr. Fearns, but the Supreme Court reversed its decision, and directed the payment of his bill.—*Medical Standard*, February, 1888.

Programme of the French Surgical Congress.—The third session of the French Surgical Congress will be held in Paris, from March 12th to the 17th, in the large amphitheatre of the Administration de l'Assistance Publique, 3 Avenue Victoria. Professor Verneuil will preside. The following questions are down for discussion; 1. The Treatment of Gunshot Wounds of Viscera. 2. The Value of Radical Treatment of Hernia as regards Permanent Cure. 3. Treatment of Chronic Empyema. 4. Recurrence of Malignant Growths after Operation: its Causes and Prevention. Surgeons wishing to take part in the Congress are requested to communicate with the General Secretary, Dr. S. Pozzi, 10 Place Vendôme, Paris. The subscription is 20 francs.—*British Medical Journal*, February 11, 1888.

A Parasitic Fœtus.—In the discussion which followed the exhibition of Mr. Owen's specimen of an anomalous sacral appendage, at the Pathological Society, Mr. Baker and Mr. Bland Sutton expressed their opinion that the appendage ought to be considered as a parasitic fœtus. Mr. Sutton also referred to an example of this monstrosity which is at present being exhibited in London. The subject, "Laloo," is a lad from Oudh, aged seventeen years, about five feet two inches in height, and of a very dark complexion. His expression is pleasing and intelligent, and his disposition very cheerful. There is no family history of any monstrosity. The mass, which appears to be of, at the most, very limited sensibility, is attached chiefly to the epigastric region. It consists of the structures forming the shoulder-girdle, including the integuments, which bear a pair of nipples; and of a second part, including the buttocks and lower extremities. The pubes is hairy, the penis well-formed, and its glans uncovered, urine occasionally passing from it. The anus appears to be imperforate. The arms are very long, like those of an American spider-monkey (*Ateles*); the but-

tocks form a projection rather bulkier than a cocoanut; the left foot hangs down nearly as low as the knee. Both extremities present numerous deformities, which cannot be satisfactorily described in this paragraph. Next to the fact that there is a large parasitic fœtus dependent from the epigastrium, the most singular feature of the case is the complete separation of the shoulder-girdle from the lower parts of the parasite. The two parts appear to be separately united to the boy's trunk by freely movable joints; they are invested by a common integument, and divided from each other by a deep groove. We understand that Mr. Sutton and Mr. Shattock examined "Laloo" on Wednesday, for the purpose of furnishing the Pathological Society with a full report of the case.—*British Medical Journal*, February 11, 1888.

Women Physicians among the Musselmen.—Three Russian women, graduates in medicine, have established a hospital for diseases of women at Koschan, Persia. Their experiment has proved completely successful. They are reported to have been consulted by 15,000 patients in the last ten months.

The Polyclinic of Humbert I.—On the 19th of January, 1888, the corner-stone of the new Roman polyclinic was laid, in the presence of the King and Queen, and a large throng. This institution is designed to represent the "Alliance of Medical Science and Civil Charity."

"Rations of Iron" for Soldiers.—Eiserne Portionen (rations of iron) is the name given by the *Militar Wochenblatt* to the canned provisions which the German soldier is now compelled to carry in his knapsack or haversack, not for immediate consumption, but for use at those times when his command is removed from the base of supplies or the quartermaster's department is short. It says: "These victuals of iron are, during war, to be used on the evening preceding a great battle; or, better, when, the army making a sudden change of front, the convoys are for a day or two retarded." Much of this canned provision is put up in America, and is said to be both better and cheaper than the German. The seventh corps (Westphalian) commanders have recently experimented with canned chocolate and cocoa, which, though seemingly light refection for a marching column, has, on the contrary, been found excellently adapted.—*Scientific American*, Feb. 18, 1888.

A New Name for Antipyrin.—Considering that the compound is not an antipyretic, but a pain reliever, and that its true chemical name, oxydimethylquinizine, is rather inconvenient, M. Nicot, a well-known pharmacist, has proposed for it the appellation *parodyne*, from two Greek words (*para* and *odune*), meaning "against pain." Thus rechristened, antipyrin could be freely prescribed and dispensed without regard to trade-mark rights. French pharmacists feel sore about antipyrin, not so much, perhaps, because it is of German origin, as because a shrewd device has enabled its makers to evade the patent medicine law and enjoy privileges denied to French pharmacists and chemists.—*American Druggist*, February, 1888.

Adulterated Candy.—The *American Analyst* of February 4, 1888, describes the adulteration practised by certain confectioners as follows:

They replace sugar and fine gum with glucose, vanilla with tonka and vaniline, almonds with myrrbane oil, butter with oleomargarine, rose with geranium, and fruit flavors with compound ethers. They "dilute" cocoanut with starch, sugar, and terra alba, and use homœopathic, and therefore harmless quantities of dyes and colors which, in ordinary amounts, are injurious, if not destructive, to the stomach. Of course, they do but little harm by most of these practices. Glucose, tonka, oleomargarine, compound ethers, and saccharated cocoanut are, if in good condition, beneficent rather than otherwise. But it is none the less imposition, humbug, and fraud. Let the confectioners adopt the English statute and stamp on every package all the ingredients their goods contain. If this were done to-day there would be the greatest commotion and the wildest excitement their pleasant industry has ever known.

Perry-Davis's Pain Killer.—The London *Medical Press* reports that the quack nostrum known as Perry-Davis's "Pain Killer" was last week expunged from the Register. The effect of this will probably be that every chemist will now have his pain-killer, and in the multitude the life will be eventually crushed out.

Milk from Sewage Farms.—Dr. Carpenter, of Croydon, denied, during a recent discussion in the Society of Arts, that the milk produced on a farm irrigated by sewage is contaminated or less wholesome than other milk. When he became acquainted with the Croydon sewage-farm, they had difficulty in getting rid of the milk, because of the prejudice against it. But by judicious management the prejudice was worn out. The speaker knew, from personal experience, that the children who took the milk were never troubled with any of those illnesses which were said to be due to bad milk, and there were never any complaints of the milk, which was delivered once a day, becoming sour. That was a proof of its power of being assimilated by the body, and that it was of a perfectly desirable character in point of health, he knew from examination of the families who took it. They had now no difficulty in Croydon with regard to the disposal of their milk from the sewage farm.—*The Popular Science Monthly*, December, 1887.

Cremation in France is in an equivocal position. Its advocates have long urged the passage of a law legalizing this method of disposing of the dead. A law passed Nov. 15, 1887, gives to any adult or minor, who is capable of making a will, the right to dictate the manner in which his funeral services shall be performed, their civil and religious character, and the mode of interment, but the conditions of the different methods of sepulture are to be decided by the municipal authorities. The effect of this last clause is that the operation of the law is suspended so far as cremation is concerned, until a decree shall be passed by the Council of State determining, under what conditions it may be permitted. The friends of cremation have persuaded the city council of Paris to urge upon the government the necessity and importance of immediately making regulations which will allow cremation to be practised. While there is progress in this direction, there is a fear that the cremation experiments recently made at the Père la Chaise Cemetery may retard the advancement of the crematory idea. These experiments have been made with the bodies of persons who had died from smallpox in Paris hospitals, and which had been

uncalled for by friends. The necessities of science require many things which are trying to sensitive feelings; they justify anatomical study and autopsies, and the unfortunate person who has neither friends nor home, may owe the tribute of his body to science for dissection. But these requirements should not exclude the respect due to death. The poor of Paris are asking what utility there can be in these crematory experiments, and they believe that the law which orders débris from operating rooms of hospitals to be cremated should furnish sufficient experimental material. Already the fear of the dissecting rooms keeps many poor persons away from the hospitals, and when the fear of ultimate cremation is added to this, it is probable that the measure will become very unpopular with the poor because of fear, and with the rich because cremation will seem to be a sign of poverty and shame.—*Sanitary News*, February 4, 1888.

The Nurses of the Paris Hospitals.—The laicisation of the Paris hospitals will shortly be complete. The religious staff at the Charité was dismissed a short time ago. The laicisation of the Hôpital Dieu and the Hôpital St. Louis will follow in the course of the year. The laicisation of the hospitals was begun in 1878, with the Hôpital Laënnec. Since that time the Administration of the Assistance Publique has organized a training school for nurses at the Hôpital de la Pitié. The nurses are taken from there to replace the religious nurses, whenever a fresh hospital is laicised. The post of superintendent of a ward is only confided to those who have obtained a certificate at the examinations, proving them competent to undertake such an office. The contract made between the Administration of the Assistance Publique and the religious orders which have hitherto supplied the hospital nurses gave the option to either side to annul the engagement if it appeared advisable.—*British Medical Journal*, February 11, 1888.

Ground-water and Health.—Mr. Baldwin Latham, C. E., declares, as the conclusion derived from eleven years of investigation, that there is generally a parellelism between the conditions of health and the volume of ground-water. The years in which there has been a large quantity of ground-water present have invariably been the healthiest years, while those in which there has been a small quantity have invariably been the most unhealthy periods. As a rule, the lowness of the ground-water indicates the future health, and not the state of health at the particular time of lowness; that is, the unhealthy period, as a rule, follows the period of low water, the degree of lowness indicating the intensity of future disease. In some instances an unhealthy period runs concurrently with the period of low water, but in all these cases there is clear evidence that percolation has begun before the unhealthy period comes on. These results, which are confirmed by observations made at Paris, differ from those obtained by Professsr Pettenkofer, at Munich, in that he there found typhoid fever and low water concurrent; in all other respects they agree with his. There is also clear evidence, derived from experience in England, that the lowering of the subsoil water by artificial means produces a tendency to the development and dissemination of typhoid fever. It is clear, however, to the author's mind, that ground-water itself has no influence, either for good or evil, upon health, but that the lowness or highness of the water in the ground is the index of conditions which greatly influence the health of all communities. We have periods of abundance of water, and periods of low water, with both healthy and unhealthy conditions. Ground-water has been shown by Professor Pettenkofer to be chemically more impure in periods of high water when the conditions were favorable to health than when there is a low state of the ground-water and a condition unfavorable to health. The records also show that we have periods when rain has started into existence malignant diseases; while, on the other hand, we have similar heavy rainfalls accompanied by a high state of public health. The records clearly point out that it is not one circumstance alone which produces disease, but that there are at least three factors concerned in the matter, especially in the case of typhoid fever, viz: the elements which produce disease, such as a polluted state of the ground; the conditions which are necessary for the development of disease, such as a period of dryness of the ground in those regions which water usually occupies, combined with a comparatively high degree of temperature; and conditions which will lead to the spread of the disease, such as the probable influence of a storm or rain in driving impurities out of the ground into our water supplies, or through the instrumentality of ground-air passing into our habitations, and its reception by a population which is in a condition to receive such germs of disease. If any of these conditions is absent, diseases like typhoid do not occur. It has been pointed out by Professor Pettenkofer that in those districts in which the rivers are held up at uniform levels by rains, the conditions are favorable to health, and cholera seldom becomes epidemic. This is corroborated in great measure by the state of health at seaside resorts, which being at the natural outflow for ground-water, and owing to the uniform height of mean tide-level are placed in a condition favorable to health.—*The Popular Science Monthly*, December, 1887.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING FEBRUARY 18, 1888.

Wasdin, Eugene, *Passed Assistant Surgeon.*—Relieved from duty at Marine Hospital, Chicago, ordered to Marine Hospital, Mobile, Ala., February 16, 1888.

Norman, Seaton, *Assistant Surgeon.*—Relieved from duty at Marine Hospital, New York, to assume charge of the Service at Evansville, Ind., February 6, 1888.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING FEBRUARY 18, 1888.

Olcott, F. W., *Assistant Surgeon.*—Detached from the "Minnesota," and ordered to the "Atlanta."

Heyl, T. C., *Surgeon.*—Ordered to the Receiving Ship "St. Louis."

Martin, H. M., *Surgeon.*—Detached from the "St. Louis," and ordered to the "Swatara."

Webster, Charles F., *Assistant Surgeon.*—Ordered to the Receiving Ship "Vermont."

Field, James G., *Assistant Surgeon.*—Detached from the "Vermont," and ordered to the "Swatara."

Whiting, Robert, *Passed Assistant Surgeon.*—Detached from the "Iroquois," and ordered to Coast Survey.

Tracy, Cloner C., *Assistant Surgeon*—Resigned, to take effect immediately.

A CASE OF LAPAROTOMY FOR RUPTURED UTERUS.[1]

BY HENRY J. GARRIGUES, A.M., M.D.,

PROFESSOR OF OBSTETRICS AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, OBSTETRIC SURGEON TO THE NEW YORK MATERNITY HOSPITAL, ETC.

ON January 21st, about 6 P.M., I was requested by Dr. H. B. McCauley to see a patient who had sustained a rupture of the uterus. The history of the case was as follows:

Mrs. M. D., thirty-two years of age, had had six children, two of which were delivered with the forceps, and she had always, as she said, "had a hard time." The last menstruation had begun on April 14, 1887. A few days before her confinement she had a bad fall in the yard.

Labor pains began during the night between the 20th and 21st of January, and Dr. McCauley was called in at noon of the 21st, at which time he found the os about the size of a dollar, the head presenting, and he noticed an extreme left lateral obliquity of the uterus. He replaced the uterus and put on a binder. The pains were quite moderate. At 4.15 P.M. the waters broke, but there was no advance of the head. At about 5 P.M. she suddenly complained of cramps in the left iliac region and began to get fretful and anxious, but gave no symptoms of shock. Dr. McCauley made an examination and found the vagina full of clots with recession of the head. He gave a hypodermatic injection of morphine and brandy, and applied bottles with hot water to her feet. There was very little hemorrhage into the vagina. The pulse was good. She was now examined by Dr. F. A. Baldwin, who ascertained the presence of an opening in the uterus through which his two fingers passed into the abdominal cavity. A medical student had also examined the patient. So far, no antiseptics were used.

The residence of the patient was a tenement house of very low grade. The apartment consisted of a room looking toward the street, used as a kitchen and sitting room, and two small bedrooms, one without any window, the other with one on the staircase. They were so small that the bed went from wall to wall, and only a narrow passage was left between it and the door communicating with the front room. In that nearest to the stairs I found the patient. She looked anxious and sullen, and it hurt her to change her position sufficiently to render an examination possible. Through the abdominal walls a large child could be felt lying to the right of the contracted uterus. After thoroughly disinfecting my hands, I made a vaginal examination and found the superior strait empty, and a large tear in the uterus communicating with the abdominal cavity. The diagonal conjugate measured four inches, corresponding to a true conjugate of three and a half inches.

After having explained to the patient and her friends that her only chance of life was the performance of laparotomy, obtained the consent of the priest, and got the necessary utensils, which had to be borrowed from all the neighbors, brought together, I performed the operation. Dr. H. B. McCauley gave ether, Dr. F. A. Baldwin assisted me, and Mr. Shannon handed instruments and ligatures.

The pubes were shaved, the abdominal wall cleansed and disinfected with soap and bichloride of mercury. An incision about four inches long was made in the median line, reaching down to the symphysis pubis. The first object that appeared in the abdominal cavity was the placenta, which lay between the anterior wall and the contracted uterus. The membranes were yet in partial contact with the inside of the womb, but were easily removed together with the placenta. The child lay to the right and presented the right nates to the line of incision. It was of large dimensions, probably weighing between nine and ten pounds. It was dead and entirely white in consequence of its exsanguinated condition. The abdominal cavity contained about a quart of fluid blood and some lumps of meconium. After the removal of the child we inspected the rent in the uterus. It comprised the whole anterior wall and part of the posterior. It was eight inches long, and ran chiefly in a transverse direction between the thick wall of the body and the thin cervix. At both ends it turned downward, and on the left side it dipped deep down into the pelvis. On this part the tear in the muscular tissue was situated an inch and a half below that in the peritoneum, the latter forming a triangular flap by itself. All hemorrhage had stopped.

We considered the expediency of performing Porro's operation, but the rent went so low down on the left side that it was impossible to form a pedicle below it and fasten it in the abdominal wall. I, therefore, simply sutured the uterus with silk (boiled in bichloride and kept in alcohol). It was quite difficult to reach the ends of the tear. I laid a double set of sutures, some deep ones comprising the whole wall of the uterus, except the endometrium, and, alternately, between them superficial ones only embracing the peritoneum, which was folded in so as to apply one serous surface to the other. As my assistant needed both his hands to make the tear accessible, he could not help me in folding the peritoneum in, and it became, therefore, neces-

[1] Read before the Obstetrical Section of the New York Academy of Medicine, February 23, 1888.

sary to put in as many as thirty-seven sutures. At the left end of the rent four or five sutures through the muscular tissue were entirely covered with the peritoneal flap, which was fastened to the corresponding edge of the part that had remained in contact with the body of the womb, thus forming a kind of *story suture*. The tube of a fountain syringe was let down to the bottom of Douglas's pouch, and the abdominal cavity washed out with plain warm water, until it returned entirely clear. Then the toilette was made in the common way, and when all was clean and dry, the abdomen was closed by uniting the peritoneal edges separately by means of a running button-hole suture of catgut, and stitching the fascia, muscles, and skin together with interrupted silk sutures. Finally, the uterine cavity was washed out with a hot solution of bichloride (1 : 5000) by means of my glass tube,[1] and an antiseptic dressing with iodoform, gutta-percha tissue, and salicylated cotton placed over the abdomen.

The patient lived four days, when she succumbed to peritonitis. This period does not present much of interest. I shall, therefore, only briefly state that a vaginal douche of a two per cent. solution of carbolic acid was given every three hours. Morphine was given hypodermatically in doses of one-fourth to one-third of a grain, repeated frequently enough to keep her free from pain. She took five grains of quinine every four hours. Her nourishment consisted of milk toast, water, and beef tea, and she was given, on an average, about eight ounces of brandy in the twenty-four hours. After the first twenty-four hours her temperature went up and down between 101° and 103° F., and reached 104° F. just before her death. The abdomen was tympanitic, and she vomited once.

She was nursed in a very unsatisfactory way by her ignorant relatives; once a drunken person visited her, and on another occasion the patient herself got out of bed. It was out of the question to obtain an autopsy, or even to become possessed of the specimen in a surreptitious way.

Rupture of the uterus is fortunately as rare an accident as it is a grave one. Dr. R. P. M. Ames[2] quotes the following figures from reports of large lying-in institutions:

Ramsbotham: Royal Maternity Charity, London,	8 cases in 48,996 deliveries	= 1 in 6124
Lehmann: Maternity of Amsterdam,	3 cases in 7,000 deliveries	= 1 in 2333
Guy's Hospital, London,	9 cases in 43,800 deliveries	= 1 in 4867
Total,	20 cases in 99,796 deliveries	= 1 in 4990

Thus there would come only one case of rupture of the uterus in nearly five thousand deliveries. In the last six years, during which I have been attached to the New York Maternity Hospital, there has been only one case in about three thousand confinements. The above is the first one I have been connected with clinically, but some years ago I made a careful macroscopical and microscopical examination of a specimen that came from a patient of Dr. L. L. Bradshaw, and was shown, by Dr. P. F. Mundé, to the New York Obstetrical Society, to which I then was Pathologist.[1]

Still, infrequent as the accident is, it is by far not so much so as might be inferred from the small number of cases published. R. P. Harris, who computes there must occur about three hundred cases of rupture of the uterus every year in the United States, has been able to collect only forty cases for the period of fifty-two years from 1827 to 1879.[2]

The question of treatment being yet to some extent undecided, it would be very desirable if every single case were published, as has been done of late years with regard to the improved Cæsarean section, laparo-elytrotomy, and Porro's operation. As we shall see later, a comparatively large number of cases have been reported within the last few years, and I have thought it might be of some interest to lengthen the list by the above reported case.

From an etiological standpoint, we notice that the patient had already gone through many pregnancies, this being her seventh confinement. Experience has shown that this is the rule. In earlier pregnancies the muscular tissue may possess strength enough to overcome an obstruction before which it succumbs when impaired by repeated gestations. Some authors have advanced the opinion that a healthy uterus never ruptures, but I can, from my own experience, corroborate the opposite view, for in the specimen on which I reported even a microscopical examination failed to discover any abnormality. Another point that perhaps may have predisposed the patient to rupture, is the fall she made a few days before delivery, but as there were no traces of any contusion or other injury, it is not likely that this factor had much to do with the rupture. No ergot had been given, a drug which seems to be very liable to become the cause of rupture. There was a lateral obliquity of the uterus, but that was remedied by Dr. McCauley. The true cause of the accident is, in my opinion, to be looked for in the disproportion between her pelvis and the child to be born. Her conjugate measured about three and one-half inches. This is a moderate degree of contraction if there was room enough from side to side, which I think there was, although the pelvis was not measured in that respect. Four times she had even given birth to her children by nature's sole efforts, although her

[2] Harris: Laparotomy for Rupture of the Parturient Uterus. Ibidem, pp. 816–817.

confinements had always been tedious and painful, and twice she had been delivered by forceps.

Most text-books lay down very precise rules for the different obstetrical procedures only based on the diameter of the pelvis, but when we think of the difference in the size of the fœtus, it becomes almost ridiculous to cavil about a quarter or half an inch difference in a diameter. Living children vary from two to sixteen pounds or more, while there is at best half such a difference in the length of the diameters. The real question the accoucheur has to weigh in his mind is the *proportion* between the child and the pelvis. One of the most difficult confinements I ever had and which was finished with great trouble by means of the cephalotribe and the cranioclast after perforation of the head of the living child, occurred in a lady with an entirely normal pelvis.[1] In the present case, the patient had been able to give birth to six children, but then there came one of unusual size, weighing at least nine pounds, and then the obstacle presented by her narrow pelvis became unsurmountable, and, no other outlet being furnished, her uterus gave way.

The symptoms seem to have been very little marked in this case, as they often are. Indeed, nothing was noticed until she began to complain of pain in the left iliac region, corresponding to the place in which the destruction was most pronounced.

The prognosis in these cases is very bad. The child almost invariably dies, and few mothers escape. It is true Joly has found 100 recoveries in 580 cases;[2] but this gives, of course, an entirely erroneous idea of the true mortality, the successful cases being much more likely to be reported as curiosities or as advertisements, than the fatal ones. The chief cause of death in the mother is hemorrhage, and the second in importance, peritonitis. The child dies, likewise, in consequence of loss of blood, or insufficient supply of blood, or strangulation of important parts in the contracting rent. In our case the appearance of the child showed that it had been drained of its blood. As to the mother, her general condition was favorable. She seemed to be a strong, healthy woman, and there were no signs of shock at the time of the operation. On the other hand, the poor residence, the insufficient nursing, the lack of intelligence in the patient, the omission of antiseptic precautions before the operation, the extension and irregularity of the tear were all circumstances that contended against a favorable issue.

The treatment to be pursued in cases of rupture is a question of the very greatest interest, which, in my opinion, cannot yet be settled. Let us first examine the earlier stages of our case, when a rupture might, perhaps, have been prevented. It would have been impossible to drag this large head through the contracted pelvis by means of the forceps. Turning might have had a better chance, and if it had been tried, and the child's head could not be brought down, it would most likely have come after perforating and emptying the cranium. Perforation of the presenting head of the living child would not have been allowed, the patient being a Roman Catholic, under absolute control of her priest. Contemplating the case in the light of the great success of the improved Cæsarean section, that would have been the operation called for. In that way, I think, both mother and child might have been saved.[1] But there is hardly a doubt that such a proposition would have met with decided protest from the patient and her friends, who would have been guided by the fact that she had borne six children *per vias naturales*.

At the time I saw the patient there could be no doubt about the line of treatment to be pursued. Laparotomy was her only chance. The uterus was entirely empty, the child and the after-birth were in the abdominal cavity, the child was large and the pelvis was small. To attempt delivery through the normal passage would have been sheer madness. To leave her alone was to devote her to sure death within a few hours, or, at best, a couple of days.

When we saw the extension and irregularity of the rent and realized how difficult it would be to suture the lower parts of it, we consulted about removing the whole uterus, and I think I would have done so, if I could have lifted the uterus sufficiently to fasten the pedicle in the wound, but this being found impracticable I undertook the tedious work of patching the torn parts together as best I could, and by using a large number of sutures I succeeded in forming a good line of union. In a case reported by Dr. C. L. Ward[2] there was found a similar peritoneal flap as in my case. He removed it, so as to avoid putting a double line of sutures. Since his patient died as well as mine, the issue cannot be used to decide which procedure is preferable. If we work with aseptic material as I did, I do not see any objection to the double row of sutures, whereas it seems less good to me to leave a large surface of the uterus denuded of its peritoneal covering.

For cleaning a cavity so large and with such power of absorption as the peritoneum I believe plain water is about as good as anything, but others have used bichloride (1 : 10,000) with impunity.

If now we leave out of consideration our particular case and speak about rupture of the uterus in general, there are two chief ways of delivery, the

[1] Since this was written, I have performed Cæsarean section in a case of generally contracted pelvis. The mother and the child are in excellent condition.

[2] Amer. Journ. Obst., 1878, vol. xi. p. 587.

one through the parturient canal, the other through the abdominal wall. The third method, that of expectation, or of doing nothing, has had its day, but since the statistics have shown that a recovery under those circumstances is so rare that it comes near being miraculous, this so-called method may be left out of consideration. The way in which nature saved the patients was by the formation of a cyst around the fœtus in the peritoneal cavity, in which it remained a harmless tenant for years, or by suppuration and the expulsion of the fœtus, either entire or piecemeal.

Ever since Trask, of Astoria, N. Y., published his memorable collection and digest of 417 cases[1] of rupture, laparotomy has been regarded by the most advanced obstetricians as the best operation. A similar conclusion was reached by Jolly, of Paris.[2] Trask's work was continued in 1881 by Dr. Ames, of Philadelphia, who tabulated 100 new cases in an excellent paper, and concluded by saying, "I would then strongly urge upon the profession the advisability of performing the operation of gastrotomy after every case of rupture, no matter whether the child had escaped into the peritoneal cavity or not." A similar appeal had already been addressed to the profession a year before by one of its Nestors, the indefatigable R. P. Harris, of Philadelphia, who followed his usual plan of first searching the records of cases in the United States, and then of securing the unpublished ones by correspondence all over the land, in which way he collected forty cases.

A priori there can be no doubt about the superiority of laparotomy over all other methods, and the innocuousness of the operation in itself when performed aseptically has become an everyday experience, but such questions cannot be settled from an aprioristic standpoint, and the statistics are misleading on account of the much greater tendency to publish successful than fatal cases.

Off and on we read yet about cases in which the child was drawn back from the peritoneal cavity, into which it had escaped, and delivered *per vias naturales*, with good result for the mother. In later years, the cavity of the peritoneum has in such cases been washed out with carbolized water and a drainage tube placed through the rent; but even before these methods were known, recovery sometimes took place in cases of this kind. In my opinion, we must be largely guided by the proportion between the size of the child, the rent, and the pelvis. There are many cases on record in which the child was easily removed by turning, but in one like the above reported it would have been impossible to do so without resorting to craniotomy of the aftercoming head, or other tedious operations, which certainly would have imperilled her life more than laparotomy.

In the *American Journal of Obstetrics* I have found ten American cases of rupture reported since Dr. Harris's article was published, namely:

1. Uriah H. Farr, Martinsville, Ind. Head in abdomen; legs seized in uterus, extraction. Death from peritonitis. (1883, p. 389.)

2. G. E. Goodfellow, Tombstone, Arizona. Extraperitoneal; breech presentation; blunt hook. Death from peritonitis. (1884, p. 930.)

3. W. E. Forrest, New York. Laparotomy, five or six silk sutures. Death from peritonitis. (1884, p. 1085.)

4. W. R. Gillette, New York. Turning, and easy extraction from abdominal cavity. Recovery. (1884, p. 1087.)

5. H. T. Hanks, New York. Turning, and easy extraction from abdominal cavity. Recovery. (1884, p. 1088.)

6. W. E. Forest, New York. Laparotomy, nine deep, and three superficial silk sutures. Death from peritonitis. (1884, p. 378.)

7. B. F. Baer, Philadelphia. Extraperitoneal; extraction by feet, from abdominal cavity. Death from septicæmia. (1885, p. 585.)

8. W. M. Polk, New York. Extraperitoneal; turning, easy extraction. Death from shock. (1886, p. 494.)

9. Charles Jewett, Brooklyn, N. Y. Laparotomy. Death; cause not stated. (1886, p. 495.)

10. T. Marx, New York. No treatment. Death from septicæmia.

In these ten cases, then, we have eight deaths due to shock, peritonitis, or septicæmia, and only two recoveries, and in both of these cases delivery was effected by turning in the abdominal cavity, and extraction *per vias naturales*, but the ease with which the latter was performed proves there was no disproportion between the pelvis and the fœtal head.

In summing up, Trask states thus the results of different modes of treatment:

	Saved.	Lost	Per cent lost.
Gastrotomy	22	7	24
Turning, perforation, etc.	38	80	68
Abandoned	15	55	78

But my impression is that we will be sorely disappointed if we expect to save 76 out of every 100 cases treated with laparotomy.

If laparotomy is resorted to, I think we ought always to suture the uterus in the way that has proved so beneficial in Cæsarean section, but we cannot expect as good a union on account of the bruised and jagged condition of the edges.

Of late years Porro's operation has in some cases been substituted for simple laparotomy, but of 8 cases so treated only 1 survived[1] This operation

[1] American Journal of the Medical Sciences, 1848 and 1856.

[1] Slawjanski in Annales de Gynécologie, February, 1886, p. 91.

causes so great a shock to the system that even in ordinary cases one-half of the patients succumb. No wonder, therefore, that when performed on a woman who is already worn out by a difficult labor and a rupture of the uterus, it has proved fatal almost every time.

Simple laparotomy causes much less shock when the woman is in a good condition at the time of the performance, and offers the advantage over all vaginal operations that it allows a much more thorough cleansing of the peritoneal cavity and even suturing of the wound, but it is anyhow a capital operation, and added to what the patient has already sustained before it is performed, will often prove too much for her. If extraction through the natural passage can be *easily* effected, be it with forceps, with or without perforation, cephalotribe, cranioclast, or turning, it may yet prove preferable to laparotomy. This can only be decided by a continued investigation of the actual results obtained since the improvements in obstetric practice in general, and especially by scrutinizing the reports of large lying-in institutions in which all cases and their treatment are reported. In cases where great difficulties are in the way of delivery through the normal passage, there can be no doubt about the advisability of performing laparotomy.

SUMMER COMPLAINT.[1]

By W. S. CHRISTOPHER, M.D.,

DEMONSTRATOR OF CHEMISTRY, AND ASSISTANT IN CHILDREN'S CLINIC, MEDICAL COLLEGE OF OHIO; PHYSICIAN TO THE HOME FOR THE FRIENDLESS AND FOUNDLINGS, CINCINNATI, OHIO.

The most striking, undisputed etiological factors of this disease are the time of life, and the period of the year when it is most frequent. The great majority of the cases occur during the first twelve months of life, and nearly all during the first two years. After this age the diarrhœal troubles in the child are not much more frequent than in the adult, and are properly classed as cholera morbus. This same period of life is the period of dentition, and it is usual to ascribe to this physiological function more or less influence in the production of the disease. The connection between the two, however, can only be that of coincidence, not that of cause and effect. If the entire freedom from diarrhœa, during the summer months, of a large number of teething children is not sufficient to overthrow this supposed cause, the fact that it is not operative in cold weather, when children cut teeth as well as during the summer, nor during the second dentition, seems to me to be a complete refutation of the dentition theory.

There is, however, something beside dentition going on during the first two years of life. This is, *par excellence*, the period of growth. At no other period of life is the body-weight, relatively speaking, so rapidly increased. It is, therefore, the period of nitrogenous food. Let us call this the albuminous age of the individual. In this we have one of the general causes of the disease.

Another general or predisposing cause is hot weather. This has been so often shown, and its influence so emphasized by statistics that further discussion of it is unnecessary.

The disease is characterized by suddenness of onset, by frequent stools, and gastric irritation. So is arsenic poisoning. So is poisoning by any gastro-intestinal irritant, whether local or systemic. The only difference between one of the mildest cases and one of the *foudroyant* cases of summer complaint is a difference of degree. Have we not here, then, instances of poisoning? If symptoms are worth anything, we certainly have.

Before attempting to answer this question more particularly, let us consider briefly some of the alleged causes of this disease. We have been told, somewhat dogmatically to be sure, that the only proper food for the infant is milk, and preferably mother's milk. Great efforts have been made to produce mixtures having the exact chemical composition of human milk, as if this would settle the difficult question of infant feeding. In all probability, the chemical composition is only of secondary importance, the main reason for the superiority of mother's milk as a food being undoubtedly its purity, its reception by the child immediately from the breast without contamination from exposure. We have no reason to believe that human milk would be any better food for the child than cow's milk, if fed from a bottle, and under the same septic conditions otherwise as cow's milk. While, therefore, admitting, of course, that breast milk is the best possible food for the infant, I should like to enter a doubt to the broad statement that milk, simply because it is milk, is the best and only proper food for the infant.

We are told that the salivary and pancreatic secretions are absent during the first six months of life, and that, therefore, the child under this age cannot digest starches, and between six months and the year digests starches only with difficulty. When we accept this statement in its entirety, we necessarily shut our eyes to what is going on around us every day, the successful digestion of starches fed to infants by mothers and nurses, the undoubted utility of such foods as arrow-root, and we also forget that diastatic power is not limited to the salivary and pancreatic secretions, and that certain bacteria, normally lodged in the intestinal tract, are capable of changing starches to sugar, and sugar to alcohol. Mellin's and Nestle's foods, even when most carefully prepared, still contain some free starch, but this evi-

[1] Read before the Cincinnati Academy of Medicine, February 6, 1888.

dently does not interfere with their utility. Nevertheless, if we can trace the slightest amount of starchy food in the child's diet, it is the custom to charge it with the causation of the diarrhœa. This is not altogether logical.

Clinical experience has shown that the use of sour milk is frequently followed by diarrhœa. Even the slightest acidity is enough to warrant the rejection of the milk as unfit for food. Probably nobody will claim, however, that it is the acidity itself which makes the milk deleterious, but that the acidity is merely the index of the decomposition which has occurred in the milk. The souring of milk is produced by the action of the lactic ferment and consists principally in decomposing part of the milk-sugar into lactic acid. Some of the casein and albumen is also decomposed into simpler substances, and a small amount of alcohol appears, but is subsequently oxidized to lactic acid. Weak butyric and alcoholic fermentations usually accompany the lactic fermentation. The frequent occurrence of butyric fermentation is especially important. When the butyric fermentation is prominent, putrefaction — that is, fermentation with offensive products—is also present. In lacto-butyric fermentation, the butyric fermentation always follows the lactic, the butyric ferment itself seeming, according to Schützenberger, to require for its nourishment albuminoids in a more advanced change than is necessary for the lactic ferment. If the butyric ferment itself is not the immediate cause of putrefactive change in albuminoids, it certainly prepares them for it, and thus facilitates the decomposition. The butyric ferment, the *clostridium butyricum* of bacteriologists, is widely distributed in nature, but has for its principal habitat sauer-kraut, sour gherkins, old cheese, and rancid butter.

Prof. Victor C. Vaughan, of Ann Arbor, who has investigated a large number of cases of milk and ice cream poisoning, has conclusively shown the cause to be a ptomaine, which he has isolated and named tyrotoxicon. Prof. Vaughan has ascertained that the tyrotoxicon is produced in milk either by the butyric ferment or a ferment always found in connection with it. So that for practical purposes we may regard tyrotoxicon as one of the products of the butyric fermentation of milk.

Physiologically tyrotoxicon produces nausea, vomiting, and purging. Chemically, tyrotoxicon, which is identical with diazo-benzol, is very unstable, and is readily decomposed by exposure to the atmosphere. It gives a deep red color with sulphuric and carbolic acids, and reduces ferric salts. The butyrate, the salt found in poisonous milk and cheese, forms needle-shaped crystals, and a potassium compound forms flat hexagonal crystals.

Tyrotoxicon is the only ptomaine which has yet been isolated from milk and milk products, and its physiological effects are identical with the symptoms of summer diarrhœa. Vaughan has reported (THE MEDICAL NEWS, vol. l. p. 673) one case of summer diarrhœa treated by him in which he found tyrotoxicon in a specimen of milk obtained the same day from the same animal as the milk fed to the child immediately before the attack.

We are now prepared to admit tyrotoxicon as a cause of summer diarrhœa, the evidence supporting this view being much stronger than any yet brought forward in favor of other alleged causes. But whether tyrotoxicon is the only ptomaine concerned in its production is not so clear. When we consider the albuminous nature of the food of the infant, and that all ptomaines are nitrogenous bases formed in the decomposition of albuminoids, and that the temperature at which the disease makes its appearance is the one most favorable to the maintenance of all fermentations, and that large numbers of various kinds of bacteria are constantly in the intestines, the possibility of other ptomaines being concerned must be considered. From clinical studies, I am inclined to believe that tyrotoxicon is not the sole cause, though a frequent one, but that there are other ptomaines and other chemical products concerned.

During the past summer, at the College Clinic, at the Home for the Friendless and Foundlings, and in private practice, I treated upward of two hundred cases of summer complaint, and it is upon the consideration of these cases that the present observations are based.

Fever is a puzzling symptom in these cases. It is present in *foudroyant* cases, and in a few of the milder ones. Why is there such irregularity in so important a symptom? Possibly in the febrile cases there is an additional ptomaine capable of paralyzing the inhibitory heat centres.

The greatest interest centres in the stools. Stools are large and watery with but little solid contents, and said to be from the small intestine, or they are small and not watery, and said to be from the large intestine. In addition, stools from the small intestine are usually accompanied by wind and pain immediately before the stool, and are shot out from the bowel with considerable force. Large intestine stools contain mucus, occasionally blood, are passed with straining, and are accompanied by pain during and after the stool. Not infrequently stools combine the characteristics of these two classes. In addition there are stools which cannot be ascribed to either of these categories; they are relatively large, soft, but not watery, and contain a great deal of mucus. The description of minor differences between stools cannot be attempted here. Owing to their incomplete character, stools from the large intestine are usually more frequent than those from the small intestine.

In color, stools vary considerably, but particular

attention should be directed to the green and the brown stools. Hayem has shown that the green stools owe their color to the presence of a chromogenic bacterium. The brown stools also probably belong to a similar category. Upon the odor of the stools they may be divided into two, possibly three, distinct classes. The odor is either putrid, sour, or the normal fecal odor intensified.

Following this, the proper clinical classification of this disease seems to be: 1. Cases in which the intestinal fermentation is putrid. 2. Cases in which the intestinal fermentation is acid.

Cases in which the odor of the stools is not distinctly putrid, but strongly fecal, belong to the first class, because as has been shown by Nencki, skatol, which imparts to normal feces their odor, is the product of fermentation resembling, if indeed it is not, true putrefaction.

It is not difficult to understand how the bacteria causing the fermentations gain access to the intestine. They may be taken down by food already tainted, or by perfectly pure food. On the contrary, when we come to consider the matter, we find that the greatest difficulty is to keep them out. Given a putrid fermentation started in the intestine, the constant ingestion of albuminous food by the infant supplies the means of keeping it up, and the surrounding conditions of heat and moisture make the intestine the best culture ground imaginable. It would be wonderful indeed, if, under these conditions, some ptomaines capable of producing physiological effects were not produced. We must not forget that the ptomaines are all alkaloids, and, like the vegetable alkaloids, some produce poisonous effects, and some do not. The ptomaine or ptomaines most frequently produced under these circumstances act like hydragogue cathartics. Others act on the large intestine more particularly. Possibly some are concerned in the production of fever.

During the early part of last summer, considerable difficulty was experienced in treating the cases of summer complaint at the Home of the Friendless. They recovered slowly and relapses were very frequent. The ventilation of the nursery was bad, and could not be improved. In looking around for a cause, it was found that the soiled diapers were thrown into a bag which hung under one of the windows. This arrangement was immediately changed. The bag was dispensed with, and the soiled diapers immediately after their removal were thrown into a tub containing a solution of mercuric chloride, and placed in the yard below, as far as possible from the nursery.

The other conditions remained unchanged, but the good effects of this move were immediately noticed. The cases improved as rapidly as could be expected, and spreading of the disease diminished. Favorable reports were also received from the laundry maids, who no longer objected to cleaning the diapers, as they were entirely free from offensive odors.

Another instance illustrating the infectious character of the trouble, and also one of its variations, is worth relating. Two infants were received at the same time at the Home of the Friendless, from the Home for Sick Children. Both these children had summer complaint, but the kind of stools that they were having were new at the Home of the Friendless. Their stools were large, soft, but not at all watery, contained a large quantity of mucus, were brown in color, had little nodules like sago grains scattered through them, and in odor the most offensive I have ever met. In a few days this kind of stool was no longer a novelty at the Home of the Friendless, three or four of our older residents having acquired that form of the disease, and considerable trouble was experienced in stamping it out. These stools seemed to indicate a different species of the disease from what we had previously had at the Home.

In the diarrhœas having acid stools it seems that the intestinal fermentation is acetic, lactic, or butyric, and that the substances acted upon are the starches and sugars. From these bodies ptomaines cannot be produced, and we can only account for the diarrhœa by the local irritation of the acid products themselves.

The only fatal case which I saw last summer was a *foudroyant* case at the Home of the Friendless.

The little patient, Gertrude, was two months old, and had been brought into the house when two days old. She was taken suddenly with vomiting, about midnight, and between then and morning had six stools, the first of which were normal, but the others were thin, watery, slimy, yellow in color, sour and offensive in odor. During this time she was given about two ounces of boiled milk with lime water, which she retained. When seen in the morning, she was pallid, wakeful but not crying, lips and tongue constantly moving, eyes and fontanelles sunken, pupils contracted, and temperature 100°. All food was stopped, and she was put on whiskey and salol. By afternoon only one stool had been passed, and this was like the others, except that the odor was putrid. No urine since morning. Gin ordered in place of whiskey and boiled water at short intervals.

By 9 P.M. the stools had lost their offensive odor. At 5 o'clock the next morning the temperature had reached 101.4°; pupils still contracted, and still no urine. By noon she had passed a small quantity of urine, and the stools, though watery, were not offensive. Her general condition, however, was very bad. Small quantities of breast milk were cautiously administered, but without success, the child dying at 6 P.M, forty-two hours after the commencement of the attack. During the last few hours she vomited once, and had several slight convulsions.

At the autopsy, made eighteen hours after death, the following was found: Post-mortem rigidity had

disappeared; it had at first been quite marked. Marked hypostatic congestion. Fingers clenched, abdomen distended. On opening the abdomen the odor was less offensive than usual, and not at all putrid. Both intestines prominent from gaseous distention, and very pale. Slight arborescence of the mesenteric vessels. Peritoneal cavity dry. The small intestine contained a small quantity of a murky yellow liquid, neither sour nor putrid in odor. The mucous membrane was very pale, except one spot about four inches long, where there was marked hyperæmia of the vessels, and redness of a Peyerian patch. Kidneys rather pale on the whole, but with red points on the cortex, and marked striation in pyramids. Liver bloody, and very friable. Bladder empty. Lungs normal, except hypostatic congestion. Heart normal. Pleural and pericardial sacs dry. Brain not examined.

Had this patient been of good stock, instead of being a foundling, she would probably have recovered. The autopsy showed clearly that all putrefaction in the small intestine had ceased, and that it was again fitted to receive albuminous food, but the little one's strength had been so far sapped that she could not rally. The suppression of urine, and the convulsions showed that so-called uræmia was present. How far this was concerned in producing the final result need not be discussed here, but it should be noted that the secretion of urine had recommenced.

Symptoms on the part of the nervous system are very common in summer complaint. The pupils are sometimes dilated but more frequently contracted. Formerly when employing the opium treatment of this affection, I thought that this symptom was due to the small doses of that drug employed. But having frequently observed it since when no opium had been administered, I am constrained to attribute it to another class of alkaloids.

In two cases seen at the clinic, and one in private practice, the following conditions were observed: In each case the child had been sick for several days with the diarrhœal symptoms of summer complaint, when it was suddenly taken ill in a different way, drowsiness, amounting to coma coming on, pupils contracted, respirations slow and shallow, and pulse very weak, and urine diminished, in each case the child seeming to be almost in collapse. In none of these cases had there been any opium given. It was evident here that the poison producing these symptoms had been already absorbed and should be eliminated. In each case an alkaline diuretic, potassium nitrate, was administered together with large quantities of water, and in each case, within four hours, a large amount of urine was passed, and all the grave symptoms completely disappeared.

It is a frequent occurrence to find a child with three or four watery stools daily, and weak, depressed, peevish, uncomfortable, evidently sick, and to find that same child on the following day, after he has had eight or nine watery stools, bright and cheerful, and evidently comfortable. The conclusion is obvious, frequency of stools is not in itself a cause of general depression. The cause of the depression is back of the stools and must be sought in the cause of the stools—that is, in the general cause of the whole condition.

Cases are occasionally met with in which there is some putrefaction in the intestine, nervous symptoms such as have been already described, and a condition of constipation instead of diarrhœa. These cases it seems proper to class under the head of summer complaint. A certain proportion of the acute diarrhœal cases become chronic. The prime cause in promoting this condition, seems to be a diet capable of prolonging the pathological fermentations, and sooner or later structural changes are produced in the intestinal mucous membrane.

In treating these cases, six objects should be kept in view:

1. The bowels should be cleared as far as possible of the fermenting masses giving rise to the trouble.

2. Substances capable of undergoing the same pathological fermentations, and therefore capable of sustaining the process, must be withheld from the patient.

3. Efforts should be made to finish by antisepsis the work left undone by the cathartic.

4. Elimination of the chemical products which have been absorbed and are producing undesirable physiological effects, should be hastened.

5. Special symptoms must occasionally be combated.

6. The stools should be carefully disinfected.

As the preliminary cathartic, the domestic remedy, castor oil, often produces excellent results, but I prefer calomel. It is certain in its action, not unpleasant to take, and possesses antiseptic properties of a high grade.

Food.—In the most severe cases, no food should be given except brandy or whiskey, for one or two days. Ordinarily it is necessary to give some food. In those cases in which the intestinal fermentation is of the putrid type, albuminous food must be withheld. Sometimes one albuminoid will be borne, when another will not. For instance, if the putrefaction has started with milk as a food, and this is usually the case, beef tea or chicken broth occasionally agrees with the patient, but their use is attended with considerable risk, and in severe cases should not be attempted. When it becomes necessary to exclude milk, breast milk should not be made an exception.

When all abuminoids are cut off, a very valuable food may be prepared by filling a bag with flour, and boiling the whole in a pot of water. The dry cooked flour in the centre of the ball is well borne

by the child. This is an old time preparation, and is not yet ready to be discarded. I have used with some success, a food prepared by thoroughly boiling crackers, and when the mixture has cooled down to about 100° F., treating the mixture with "Maltine." This cracker food is not entirely free from nitrogenous constituents, the crackers containing about twelve per cent. of albumen, but it has a practical value which overcomes this theoretical objection. As a test of this food, before the hot weather came on last summer, I put a five months foundling upon it, and kept her on this food exclusively for four weeks. At the end of this time she had gained slightly in weight, notwithstanding the fact that she was syphilitic to the degree that she had suffered destruction of the bones of the nose, and had a gumma. This was proof enough that life could be supported on it through a short period.

When the intestinal fermentation is of the acid type, the food to be allowed is not so easily found. The sugars and starches must be withheld. Milk, ordinarily classed as an albuminous food, contains sugar, and if administered under these circumstances not only feeds the acid fermentation, but soon adds to it an additional putrid fermentation. This change is frequently observed clinically, and seems to be due to the occurrence of the lacto-butyric fermentation. Beef tea, animal broths free from starches, and peptones, are the only safe foods to give under these circumstances.

Antisepsis.—Thus far I have been somewhat disappointed in the results of intestinal antiseptics, and must class them as inferior in importance to the preliminary cathartic, and to the proper selection of diet in these cases. They play an important role, but not the most important role in the management of summer complaint. In this connection I wish to call attention to the very valuable paper of Dr. L. Emmet Holt, on "The Antiseptic Treatment of Summer Diarrhœa" (*N. Y. Med. Journ.*, Jan. 29, 1887). With the statements of Dr. Holt's paper I can heartily agree, except as to a few minor and relatively unimportant matters. As intestinal antiseptics, I confined myself last summer to mercuric chloride and salol. This latter substance, which is said to be decomposed into salicylic and carbolic acids after reaching the small intestine, would seem to be particularly adapted to intestinal antisepsis. On the contrary, I found it rather uncertain in its action, occasionally doing all that could be expected, but much more often not. It is usually absorbed as salol, and patients using it soon exhale from their whole bodies its peculiar odor.

Mercuric chloride is not satisfactory, except when given in injection in rectal troubles.

With the other antiseptics I have, as yet, no experience in this disease.

I wish to lay particular stress upon the use of diuretics. Their value in severe affections is sufficiently shown by the cases already mentioned, but in milder cases they play an important role in controlling or alleviating certain nervous symptoms. The alkalies and water form the best diuretics for this purpose.

Pain, when severe, must be met with opium. Opium, with bismuth, is again indicated when the number of watery stools becomes so great as to endanger life, but this condition, I think, arises only rarely. Free purgation is essential to the treatment of this disease on the plan herein indicated, and the opium treatment cannot be consistently employed with it. With the opium treatment of the disease it is very easy to control quickly all the symptoms and make the case at once present a much improved appearance, but the good result is more apparent than real, and the old train of symptoms soon sets in again.

In conclusion, that to which I wish particularly to direct attention, is:

1. The recognition of the two forms of pathological intestinal fermentation met with in summer complaint, and the classification of the cases in accordance therewith.

2. The selection of diet based upon this classification.

3. The use of diuretics in cases of summer complaint presenting undesirable symptoms on the part of the nervous system.

4. Disinfection of the stools.

FOREIGN BODY IN THE BLADDER: REMOVAL BY MEDIO-LATERAL CYSTOTOMY.

By ALBERT L. GIHON, M.D.,
MEDICAL DIRECTOR, UNITED STATES NAVY.

The paper read by Dr. DeForrest Willard before the Philadelphia County Medical Society (The Medical News, November, 1887) on the removal of foreign bodies from the urethra and bladder, and the cystotomy, performed for this purpose, reported by Dr. W. W. Keen to the same body (The Medical News, January 14, 1888), may cause the recital of the following case to have a pertinent interest:

D. D., oiler, native of Ireland, aged thirty-one years and five months, admitted into U. S. Naval Hospital, Mare Island, California, from U. S. Ship "Marion," November 1, 1887, as with "foreign body in bladder." The hospital ticket contained the following history of the case:

"On September 18th, presented himself saying that four days before (September 14th) he had passed a pine stick (thickness of a Faber lead-pencil and 4¼ inches in length) into his urethra. He attempted its removal with a gimlet and broke 1¼ inches from further end of stick, which entered his bladder. After suffering agony for four days and frequent severe chills, he revealed his condition;

after which the stick (three inches of it) was removed by perineal section. In fifteen days, the perineal wound healed, but about half of the scrotum sloughed away with great fetor. Nature repaired this loss and he is apparently well, but the fragment of stick yet in his bladder is causing pain, hemorrhage, and stoppage of urine. He is sent to hospital to have this foreign body removed."

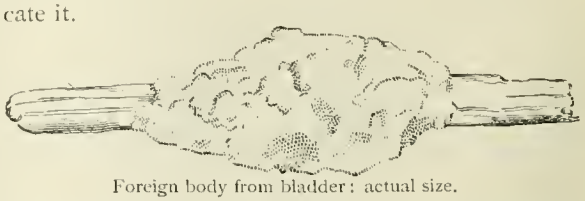
On admission to hospital he entered the service of Passed-Assistant Surgeon Norfleet, from whose notes the following clinical history is collated:

Patient states that there is a stick an inch and a quarter long in his bladder, which sometimes arrests the flow of urine during micturition, and toward the latter part of the act blood is passed; suffers pain only at neck of bladder; wound resulting from former operation almost healed, leaving only a small citatrix behind the scrotum, about an inch anterior to the bulb; no evidence of loss of soft parts by sloughing; foreign body readily discovered in the bladder by bougie à boule.

November 29. Patient was put under ether by Passed-Assistant Surgeon Lewis, and Medical Director Gihon, assisted by Passed-Assistant Surgeon Norfleet, Assistant Surgeon Harris, and Drs. Mathis and Fallier, of the French Navy, performed median cystotomy, reaching the bladder without difficulty, but it was found impossible to extract the foreign body and the median was changed to lateral (left side). The foreign body was found lying crosswise superiorly and could not be grasped at once, but after much manipulation and pressure above the pubes it was finally seized with the forceps and extracted. It proved to be a piece of penholder, *three and a quarter inches long*, incrusted with phosphates, forming an irregularly spindle-shaped mass, with three-fourths of an inch of the stick projecting at each end, one of these ends being broken and jagged. The incrustation was one and three-quarters of an inch long and three-quarters of an inch in diameter at its thickest part, and very rough. The operation lasted two hours and a half, and was attended with a great deal of hemorrhage. By the following morning most of the urine passed through the urethra, and by December 12th the wound was almost healed, no urine issuing through it, and a good stream passing through the urethra not oftener than in health.

December 16. Discharged from hospital, not one unfavorable symptom having occurred, and no other antiseptic precautions having been observed than the immersion of the instruments and rinsing of operator's hands in a 1 : 2000 solution of mercuric chloride.

The figure represents the size and appearance of the foreign body, which were unexpected in view of the positive statement of the medical officer signing the hospital ticket, at the transfer of the patient, that only one and one-quarter inches of the stick had passed into the bladder. Its spindle-shape caused the body to lie transversely just beyond the reach of the forefinger after the dilatation of the wound to its extremest possible extent, where it rotated upon its axis, thus eluding the attempts to seize and extricate it.



Foreign body from bladder: actual size.

Notwithstanding the success of the operation and the healing of the wound without drawback, after the necessarily severe and protracted manipulations, I still regret that I had not adhered to my original intention of opening the bladder above the pubes, which the size and shape of the incrusted stick and the very great difficulty attending its extraction prove to have been the proper procedure.

The case is here reported as evidence of the preference which should be given the high operation under similar circumstances.

HOMATROPINE HYDROBROMATE.

A Study of its Clinical Value in Ophthalmology.

By JOHN S. STEWART, M.D.,
of Philadelphia.

In an endeavor to bring this subject unbiassedly before the profession, the author has carefully gone over all the current literature, and extracted what seems correct. These researches he has embodied in the present paper, and from them drawn certain conclusions.

ACTION ON THE CILIARY MUSCLE.

First. Single instillations of either the one-twentieth or the one-fortieth of a grain of homatropine hydrobromate are insufficient to paralyze the accommodation (Oliver).

Second. Repeated instillations will paralyze the accommodation. The minimum amount thus found to be capable of producing *complete* paralysis of the ciliary muscle in an emmetropic eye is the one-fifteenth of a grain, in two instillations of the one-twentieth and the one-sixtieth of a grain each, the latter quantity being instilled at the time of the former's greatest intensity of action (thirty-two minutes after the first instillation).

Third. The maximum amount of the drug recommended and used in repeated instillation for the purposes of examining refraction, so far as has been reported, is a solution of gr. xxiv to the f℥j, two to three instillations being required in most cases to paralyze completely the accommodation.

Fourth. Complete paralysis of the ciliary muscle following single or repeated instillations is found to be established in from twenty to ninety minutes, the time depending to a great extent on the amount of the drug used.

Fifth. Careful study of some of the reported cases

where a sufficient amount of the drug had been used to paralyze the ciliary muscle, distinctly shows that the fine distinction of astigmatic angles and the estimation of degrees of astigmatism were not positive, and, in some of the reported cases where other mydriatics were afterward employed, varying amounts of ametropia could be found in excess of what had been measured when the homatropine was used.

Sixth. The duration of the local paralysis is variously estimated to be from thirty minutes or longer to several hours.

Seventh. In cases where the loss of ciliary power was complete, the muscle regained its full action in from ten to seventy-two hours—the time being directly dependent, in the majority of cases, on the amount of the drug used.

ACTION ON THE IRIS.

First. Single instillations of the one-twentieth of a grain of hydrobromate of homatropine, in the majority of cases, are capable of producing complete mydriasis; whilst it is impossible to obtain maximum dilatation by means of single instillations of one-fortieth[1] of a grain (Oliver).

Second. Repeated instillations cause maximum dilatation of the pupil in the majority of cases. Keyser has observed that the weaker instillations of the drug do not dilate *ad maximum*, whilst the stronger ones, by the irritation which they produce, occasionally cause antagonistic action in the circular fibres of the iris, the result being some contraction of the pupil.

Third. The return to normal of the pupillary diameter is found to take place in thirty and fifty hours respectively after single instillations of the one-fortieth and one-twentieth of a grain are made. The time given by Völckers after the instillation of a one per cent. solution is from twelve to twenty-four hours.

ACTION ON THE CONJUNCTIVA.

First. Single instillations of either the one-fortieth, or the one-twentieth of a grain of an absolutely neutral salt are not productive of conjunctival irritation (Oliver).

Second. Repeated instillations cause irritation and hyperæmia of the conjunctiva (Schell, Keyser, Oliver, Jackson and others).

Third. In a few instances, as noticed by Keyser,[2] and others, acute conjunctivitis has followed repeated instillations of the drug, especially of the stronger solutions.

ACTION ON THE INTERIOR OF THE EYE.

A certain amount of choroido-retinal irritation, accompanying the use of homatropine has been observed by Risley and others.

ACTION ON THE GENERAL SYSTEM.

First. Tweedy and Ringer have shown the special action of homatropine to be on the nerve centres, especially the spinal cord. The effect on the heart, as found by them and observed by Hare, was slowing, accompanied by irregularities of force and rhythm.

Second. Toxic symptoms never follow single instillations of minimum amounts of the drug.

Third. Repeated instillations of the quantities noted by the various authors are not frequently accompanied or followed by constitutional disturbance, the few such cases reported being limited to "hallucinations," "incoherency of speech," "drowsiness," "intoxication."

CONCLUSIONS.

First. Single instillations of less than the one-fifteenth of a grain of hydrobromate of homatropine are of no value for the correct estimation of ametropia.

Second. On account of the quick return of the ciliary power and normal size of the pupil after single instillations of the one-fortieth of a grain or less, of hydrobromate of homatropine, this drug is extremely useful in cases where an accurate ophthalmoscopic examination of the media and fundus of the eye is desired.

Third. As a single instillation of an absolutely neutral salt does not act as an irritant, the drug may be thus employed for purposes of precision, even in cases where local irritation exists.

Fourth. On account of the constant local irritant action of repeated instillations of hydrobromate of homatropine, this drug may be considered harmful in certain cases of inflammatory disease, or traumatic lesion of the ocular coverings and tunics.

Fifth. The fact of the constant irritant action of repeated instillations of homatropine hydrobromate on the deeper tunics of the eye, the choroid, and probably to a certain extent the retina, gives answer in great measure why ametropia cannot be properly estimated; hence the drug should be avoided in the correction of refractive error.

I here desire to express my thanks to Dr. Charles A. Oliver for many valuable suggestions and assistance given in the preparation of the present paper.

1617 Arch Street.

[1] Hotz claims to have obtained complete dilatation by the instillation of a single drop of a one-half per cent. solution.

[2] In a recent article this author states that the use of a perfectly neutral salt, "thoroughly washed from all free acid," does not cause the irritation he first observed.

THE TOPICAL APPLICATION OF OIL OF TURPENTINE TO RECENT WOUNDS,

With Observations Relating to the Germ Theory of Disease.

By ROBERT B. S. HARGIS, M.D.,
SURGEON TO THE PENSACOLA HOSPITAL, PENSACOLA, FLORIDA.

From the very interesting paper in The Medical News of November 19, 1887, page 601, in reference

to Holmfeld's experiments with the oil of turpentine, we learn that for some hours after the application of oil of turpentine to various kinds of germs, and particularly to fresh colonies of *micrococcus prodigiosus* and *staphylococcus*, its effects on their life and growth are *nil*. Hence it is evident that turpentine, unless applied in large amounts for a considerable time, produces no sufficient effect to encourage our use of the drug for the purposes of antisepsis.

The writer has for many years applied the oil of turpentine in almost every case of external injury involving a solution of continuity of hard as well as of soft parts, with the effect of preventing suppuration and sepsis, and hastening the process of repair. For example, a recently maimed hand or foot is presented, in which certain tissues, integuments, muscles, nerves, bones, etc., are involved to an extent a little short of necessitating amputation. After the removal of all foreign bodies, every fragment of bone and necrosed tissues, and other parts likely to die, effusions of blood are stopped, and every visible clot is cleared away, and after free lavation with hot water —about 101° F. — the parts made as dry as possible by a clean, soft sponge, are properly adjusted and covered with pledgets of lint or absorbent cotton saturated with the oil of turpentine; adhesive plaster may now be useful or necessary, and a careful application of a muslin roller bandage completes the first dressing. A compound of two parts of oil of turpentine and one of linseed oil, thoroughly mixed, is now applied over the site of the wound to repletion, and reapplied at certain intervals, so as to keep it constantly saturated. By this manner of dressing, the wound will remain free from indications of putrefaction for an indefinite time. I have known this dressing, in the case of an amputated finger, to be retained nine days, and when removed emitted no other odor but that of the turpentine and linseed oil, and the cut surfaces had united by first intention.[1]

In all my amputations I now use animal ligatures, and cut them off near the knot, the flaps or incised surfaces are brought together with care, and retained by adhesive strips, without *the aid of stitches*, and supplemented by muslin rollers carefully and neatly applied, with excellent results. The manner of using adhesive plaster is of no little moment, for either of the extremities; for an arm or a leg, the strips should be cut nicely even, one-half an inch in width, and long enough to extend four or five inches on both sides of the base of the flaps; a strip about five inches wide should encircle the stump so as to embrace the ends of the narrow strips neatly. Of course, the length and breadth of the strips are varied according to circumstances. Treated by sealing in this way hermetically, as it were, other wounds besides those of amputation are not only "unmistakably safe," but the reparative process is absolutely favored. The following cases very well illustrate the results of the treatment of wounds and amputations above indicated:

Case I. — William S., aged thirty-five years. Amputation of the arm necessitated by a gunshot wound of the hand and forearm, which was attacked by gangrene. The amputation wound united by first intention, under the turpentine dressings; but at the inner part of the *cicatricial* line it healed by granulation, while the other part healed by first intention. This difference in result is explained by the fact that although the wound had healed along the entire line, showing a nice narrow cicatrix, a few weeks afterward a small abscess formed near the inner point of the line of union, and terminated in a little sinus, through which a spicula of bone soon made its way out, leaving a healthy but rather ugly scar.

Case II.—John H., aged thirty-two years. Partial amputation of the hand. In the act of coupling railway cars, all the fingers from their ends up to the metacarpo-phalangeal articulations were literally *mashed*, and two lacerated wounds appeared, but little jagged, extending from near the wrist longitudinally and parallel to one another, through the palmar integument, down to the fascia, and out to the mashed fingers. Of course amputation was inevitable, and I operated through the distal third of the phalanges of the metacarpal bones, and obtained excellent flaps. Five or six vessels were ligated with animal ligatures cut off near the knots. The flaps were carefully brought together and held in coaptation by narrow adhesive strips and a roller bandage. The oil of turpentine had its place in a strip of lint, over the amputation wound before the bandage was applied, and the compound of turpentine and linseed oil came in for its share of usefulness. The dressings were allowed to remain intact ten days, and when removed the wound was found cicatrizing nicely, and in less than another ten days was well, in spite of irregular habits and whiskey. The thumb is now useful, and a *sine qua non* in his daily work.

Case III.—William R., aged fifteen years. Lacerated wound of the index finger of the right hand, by gunshot. The parts of the member hung together by a few muscular fibres, tendons, etc., and all of the middle third of the bone had been carried away except a few splinters. I had determined to amputate, but the boy plead so earnestly that an effort should be made to save it, and, on reflection, considering that a few bundles of muscular fibres and tendons were intact, and that a branch from the *arcus sublimus* was in continuity, I yielded, and dressed the wound carefully in my usual way. Repair was completed in about three weeks, and the patient had a useful and by no means an ugly finger.

Now, what are the relations of this practice to the germ theory? Why do not wounds under the treat-

[1] The oil of turpentine prevents the free exudation of serum, which generally flows for some time after amputation, and always deprives it of putrefactive and irritating qualities.

ment indicated suppurate? Why do they not have the odor of putrefaction? Why do they heal kindly and speedily?

I shall not essay to answer these questions, because the attempt would involve a discussion beyond the limits of this paper. But it is certain that as a preventive of septic influences on wounds, even if it fail to destroy various kinds of germs besides the *micrococcus prodigiosus* and *staphylococcus*, nothing better has yet been discovered that can be used in every-day practice, or is more handy or more efficacious than the oil of turpentine, not excepting the 1 : 1000 solution of the bichloride of mercury.

MEDICAL PROGRESS.

The Treatment of Follicular Tonsillitis.—Boisliniere reports seventy-five cases of follicular tonsillitis treated with benzoate of sodium, as follows:

In treating these cases no local application whatsoever has been used—no gargle prescribed. We have simply used the following formula:

Benzoate of sodium . . .	ʒ j–ʒ iv
Glycerine,	
Elix. calisaya bark . . .	āā ʒj. M.

Sig.—One teaspoonful every hour or every two hours.

In the analysis of seventy-five cases, being the last seventy-five treated, we find that:

1. By the use of the benzoate of sodium the disease is cured in from twelve to thirty-six hours, a great gain in time, as the average duration of the disease has been heretofore from two to five days. (Mackenzie.)

Of the seventy-five cases,

41 reported well in 12 hours,
31 " " 24 "
3 " " 36 "

Average, 20 hours.

In private practice, when the cases could be watched more carefully, we have frequently seen the white cheesy points disappear in from eight to ten hours.

2. That the benzoate of sodium undoubtedly controls the febrile elements in the disease.

3. That it may be given with impunity, even to children; we have never been able to discover any bad or even disagreeable effects from its action.

4. That it is a valuable addition to the remedies used in throat affections, especially in an acute inflammatory condition of the tonsils, when applications only aggravate, and gargles increase the trouble.—*St. Louis Courier of Medicine*, February, 1888.

Tobacco Amblyopia.—From the study of forty-nine cases of this affection, Browne reaches the following conclusions:

1. The optic nerve resembles a sensory tract of the spinal cord, consists of two tracts, of which the central has a special affinity for tobacco, while other drugs—*e.g.*, quinine—will leave it unaffected.

2. Tobacco is the essential agent in causing an axial neuritis, which does not in ordinary cases tend to spread to the nerve-fibres coming from the peripheral retina.

3. As a rule patients apply in the early stage of neuritis, and complete recovery may be expected without any treatment except entire cessation of smoking.

4. When recovery is established, moderate smoking is not injurious.

5. Although it would be absurd to suppose tobacco is the only agent capable of causing axial neuritis, no other has yet been substantiated in a series of cases arising in strictly non-smokers.

6. Besides tobacco a special condition is required to precipitate an attack; alcohol, diabetes, excessive venery, starvation, mental shock or distress, are the most common auxiliaries.

7. In some persons a special tendency to degeneration (sclerosis or atrophy) exists hereditarily; to these tobacco is especially injurious.—*Liverpool Medico-Chirurgical Journal*, January, 1888.

A Draught to be administered in Delirium Tremens.—Savignac prescribes the following:

Gum arabic water,	
Claret	āā ʒ 15
Syrup of tolu	ʒ 7½
Aqueous extract of quinquina . .	ʒ 1
Tincture of musk	♏ 75.

A teaspoonful hourly.—*Revue de Thérapeutique*, Feb. 1, 1888.

An Unpleasant Effect from Saccharin.—Hedley reports, in the *British Medical Journal* of February 11, 1888, the following case:

In a case of glycosuria I had prohibited the use of sugar, and substituted saccharin, with apparently excellent results; but after about twelve or fifteen doses had been used, my patient began to feel so much nausea that he was obliged to leave off taking it. His mouth got to have an "abominably sweet taste always in it," and, without the addition of any sweetening material, everything he touched tasted of saccharin; indeed so pronounced was this that his pipe, usually such a solace, had to be given up in disgust, on account of the smoke having such a sweet flavor.

This intensity of sweetness occurred on the fifth day after beginning the saccharin; and probably an explanation will be found in the fact that it passes unchanged through the system, and will, I am afraid, produce a sweet saliva, unless it is used with occasional intermissions.

The Toxicity of Boric Acid.—Gaucher has made recent investigations on the extent to which boric acid may be safely administered. He estimates that to poison an adult a dose of 2½ ounces must be given daily for 10 days. He has used it externally, as usually done in skin diseases, with good results, and has prescribed it internally in phthisis, in doses of 8 to 15 grains daily, with advantage.

As it is eliminated by the kidneys, he suggests its internal use in cystitis, thus avoiding the irritation produced by catheterization.—*Gazette Médicale de Paris*, February 4, 1888.

Benzol in the Treatment of Whooping-cough.—MACALISTER, in the *Liverpool Medico-Chirurgical Journal* for January, 1888, reports his experience in the use of benzol in whooping-cough, as follows:

The greater number of children who came under notice had had the disease for two or three weeks, some being in the stage of full development, and a few in the stage of decline. In many of these the benzol appeared to be effective, lessening the frequency of the paroxysms, rendering them less distressing, and also perhaps hastening the time of recovery, the improvement in some cases being so marked and rapid as to leave but little doubt in my mind that it was accelerated by the remedy employed. In these cases in which the benzol was given during the first fourteen days of the "whooping" stage, one cannot with certainty say that any benefit immediately followed its use; the paroxysms were not apparently diminished in number, although perhaps they were shorter and less distressing, but in the third week and in the period of decline the drug appears to be useful.

Benzol is insoluble in water and will not mix with it even with the addition of mucilage, but if a little rectified spirit (in which it is freely soluble) be added to a thin mucilage, together with some simple syrup and a few minims of tr. chloroformi co., an excellent mixture is produced, which is readily taken by children. The dose of benzol is from ♏ij to ♏vj or more, and the formula I have used is as follows:

R.—Benzol (pur.)	♏ij.
Sp. vini rect.,	
Tr. chloroformi co. . . .	āā ♏ijss.
Syrup. simp.	♏xx.
Mucilag.	ad. ʒj.

Dose, ʒj–ʒiij, according to age.

Chloride of Methyl, Locally, as an Anæsthetic.—BAILLY has found that tampons saturated with chloride of methyl are a convenient and efficient means of producing local anæsthesia by refrigeration. He has devised a simple apparatus by which chloride of methyl may be kept in a liquid condition for several hours, transported conveniently, and applied by tampons or a brush. With suitable precaution, this method of anæsthesia may be applied to mucous membranes.—*Gazette Médicale de Paris*, February 4, 1888.

Hydrobromate of Hyoscine in Mania.—THOMPSON, in the *Lancet* of February 4, 1888, reports his use of the drug as follows:

The chemists prepared at my request a solution containing a grain in 400 minims. I fixed upon this strength, so that in the event of a moderate quantity being given in mistake for the same of a solution of morphia no particular harm would be done. The dose of this solution is from two minims (1–200th of a grain) to four minims (1–100th of a grain). As much as six minims have been given, but the patient is made so "drunk" that the smaller doses are preferred. My colleagues and I have used the new drug in many cases, but we find that while on all occasions it acts as a certain hypnotic, it is of most use in cases of chronic, and recurrently chronic, mania. The effect on the sexes is about the same. There is marked sluggishness of all motor functions, with depression of reflex activity, and dizziness, dimness of vision, an ataxic gait, and dryness of the mouth and fauces. All these symptoms are but faintly seen when only a proper medicinal dose has been given. The drug has been used here, as I have said, in very many cases, and I can say that on no occasion have we failed to produce the desired effect. The patient is quieted and falls asleep, but the sleep is not very deep of its kind, and at any stage there is no difficulty in rousing the patient to the fullest extent of wakefulness, though he soon falls asleep again. In acute mania, where much restlessness and tendency to knocking about are the chief symptoms, it acts most beneficially. The patient comes to his senses and rests quietly, and so time is gained and exhaustion avoided.

The Treatment of Bronchitis.—FERRAND has prescribed creasote as follows:

R.—Creasote	gtt. 3.
Essent. limon.	gtt. 2.
Aquæ	gtt. 120.
Syrup. aurant. flor.	gtt. 30.

A teaspoonful of such a mixture may be taken every two or three hours.—*Journal de Méd.*, January 22, 1888.

The Effects of Strophanthus.—ROSENBUSCH, of Lemberg, concludes from his clinical studies on the use of strophanthus, that it possesses a marked influence upon the heart, increasing the force of the systole, prolonging it, raising arterial tension, and slowing heart action. It strengthens the heart muscle and regulates its action. It possesses a distinct, but very slight, diuretic power. It disturbs digestion less than the heart tonics in general use. It may be used for several weeks without symptoms of cumulation. The best form to be prescribed is simple tincture, in doses of from 10 to 25 drops three times daily.

It may be given with advantage when digitalis does not agree with the patient, and in cases of severe disturbances of compensation it may be used to maintain the effect of digitalis. The alcoholic tincture is superior to the ethereal tincture, because it contains the glucosides from the plant, while the ethereal tincture is more likely to disturb digestion.

It should not be used in stenosis of the aortic valves, because it prolongs the cardiac systole.—*Berliner klinische Wochenschrift*, February 13, 1888.

Sour Milk in Summer Diarrhœa.—The *Medical Press* of February 8, 1888, writes that the house-surgeon of the Prison Zweibrücken, DR. OSTHOFF, has in two annual reports spoken very favorably of the employment of sour, curdled milk in summer diarrhœa, in adults as well as in children. Such teaching may seem startling to the English mind, with its prejudice against using milk having about it any suspicion of sourness, and especially as an article of food for infants. It should be borne in mind, however, that England is perhaps the only country in the world in which such a foolish prejudice exists, and in which sour milk is not considered at least as wholesome as milk that is sweet. But this by the way. Dr. Osthoff endeavors to explain the beneficial action of sour milk in the following way. He believes that the bacilli of sour milk destroy and overcome, by their rapidity of growth, the other microörganisms that are the cause of the diarrhœa, and that they thus bring the process to a

standstill. In addition to its value as a dietetic agent in summer diarrhœa, it proved exceedingly useful "in all chronic abdominal affections associated with dyspepsia, in chronic intestinal and hepatic diseases with diarrhœa, or constipation, in jaundice, and as an article of diet in typhoid, pneumonia, and erysipelas. In tuberculosis of the intestines, however, it increased the diarrhœa. It forms a valuable means of support to Oertel's treatment in cardiac cases, and cases of emphysema, in small quantities as a substitute for coffee, wine, beer, and water, as a thirst-quenching drink, as well as a food containing both muscle- and fat-forming material in one and the same form. At the instance of the Bavarian ministry, Prof. von Voit worked out an official report on this sour milk therapeusis, and from this some interesting details may be extracted. Sour milk very much resembles fresh milk as a food (four per cent. albumen, three per cent. fat, four per cent. sugar). The use of it is to be recommended as an addition to the needful amount of hydrocarbons. Moreover, especially in summer, it forms a refreshing drink, and may be ordered with advantage in dyspepsia. The action of sour milk is very varied; sometimes it causes constipation, and sometimes diarrhœa. For this reason he recommends that in infantile diarrhœa it shall be used with caution. In general he recognizes the value of sour milk as an article of diet. A writer in the *Deutsche Medizinal Zeitung*, commenting on the above, draws attention to the similarity of sour milk and kefir, and let us add the imitation koumiss, now so familiar. Both are used in phthisis. Koumiss at one stage (when fresh) is known to relax the bowels, whilst at another it constipates. It is the same with kefir, and doubtless it will be the same with sour milk, as it gets older it becomes more constipating. We think Dr. Osthoff has done well in drawing attention to a neglected and very useful article of food.

Amylen Hydrate.—In the clinic of Schreiber, Gürtler, at Königsberg, reports his results in sixty-one cases of various conditions, in which he used amylen hydrate as a hypnotic.

The cases included alcoholism, encephalomalacia, morphiomania, epilepsy, and tuberculosis. His prescriptions were as follows:

Amylen hydrat.	grs. 105.
Aquæ dest.	ʒ 10.
Syrup of raspberries . . .	ʒ 7½.—M.

Half of this to be taken on retiring.

Or,

Amylen hydrat.	grs. 105.
Aq. menth. pip.	ʒ 10.
Syrup of raspberries . . .	ʒ 7½.
Ol. menth. pip.	gtt. 1.—M.

Half to be taken on retiring.

The dose of amylen hydrate ranged from 50 to 90 grains. Gürtler obtained less uniform results in children than in adults, with this remedy, in proportionate doses. He considers it less apt to induce cardiac failure than chloral hydrate.—*Berliner klinische Wochenschrift*, Feb. 6, 1888.

The Immediate Closure of Tracheal Wounds.—Sir William MacCormac writes to the *Lancet* of February 4, 1888, his opinion on this subject as follows:

In support of your editorial remark on the advantages of immediate closure by suture of tracheal wounds, I would refer to a case published in the *Lancet* of January 2, 1886, where the blade of a broken tooth-forceps was extracted from the right bronchus. The incision in the trachea was an inch and a half long, and this I carefully closed by suture. The external wound was also closed after drainage tubes had been introduced. I am convinced this proceeding materially contributed to the successful issue of the operation, by shutting out the cold air from the lungs and preventing wound secretions entering the trachea. It will not be always desirable to close the tracheal wound, but in those instances where an operation is performed for the removal of foreign bodies from air passages, in some cases of suicidal wound, and generally where the conditions for local repair are favorable, there are obvious advantages to be gained by the immediate suture of the tracheal wound.

Children's Food in Typhoid Fever.—Jacobi, in the *Archives of Pediatrics* for February, 1888, recommends the following mode of treatment: Typhoid fever is of long duration, its temperature is sometimes quite high in children, as it is in adults. The small intestine is affected principally. Thus, not only is, after the first few days, a considerable amount of food required, but it must be so chosen as to be digestible in the stomach; its proper selection is the more important the more the latter organ is impaired by high temperatures. Beside plenty of water, or acidulated water (hydrochloric, no organic, acid), albuminoids are indicated. Milk and cereals (in decoctions, which must be strained) are the proper foods. The administration of stimulants, both as to quantity and to time, depends on the character of the individual case, and the power of resistance on the part of the patient, beside the condition of the heart. When the latter becomes feeble at an early period, beside heart-stimulants (digitalis, spartein, caffein, camphor), alcoholic stimulants are required. Diarrhœa demands (beside opium, naphthalin) albumen, rice-water, arrow-root, mutton-broth. Hemorrhage forbids food in any shape for a time, the duration of which depends on the general condition of the patient. At no time during the disease, and during the first ten days of fully established convalescence, the food must ever be solid. No vegetables must be allowed until three weeks have elapsed since the beginning of apyrexia. When the milk and cereal food become distasteful, a change in their preparation will and must suffice. The large majority of relapses are due to a dereliction in the strict rules of feeding.

An Emulsion of Terebene.—England, in the *American Journal of Pharmacy* for February, 1888, reports the following formula:

℞.—Terebene,

Ol. gossyp. sem. . . .	āā ♏clx.
Pulv. acaciæ	ʒvj.
Pulv. sacchari	ʒij.
Aquæ q. s. fiat. . . .	f℥iv.—M.

Dose, 1 to 2 teaspoonfuls (=10 to 20 drops).

The product is a milk-white, perfectly suspended liquid, having the odor and bitter, turpentine-like taste of terebene, and is miscible with water, without separation.

Alum in Typhoid Fever.—DR. PAOLETTI has treated sixty cases of typhoid fever, with excellent results, with crude alum alone. He remarks that this drug has formerly been used only as a styptic and an astringent, but now that its antiseptic properties have been recognized it is clearly indicated as a remedy for abnormal fermentations in the intestinal canal.—*British Medical Journal*, February 4, 1888.

A Case of Macroglossia, with Partial Resection.—TAKAKI, of Tokio, reports, in the *Sei-I-Kwai Medical Journal* for January, 1888, the following case of macroglossia, on which he operated in the Tokio Charity Hospital:

The patient, a boy, aged two years and two months, was admitted on the 18th of October, 1887, with the following history: About the 10th of August, 1887, he was taken ill with sudden rise of temperature, sleeplessness, violent screams, etc., without any known cause, so that his mother thought he had caught "cold," but soon his tongue became much enlarged, protruded from his mouth, accompanied with some pain, and, at the same time, saliva increased in quantity, moistening the parts about the mouth and the clothing and interfering with mastication.

State on admission: The nutrition fair, slightly pale. Tongue enlarged, protruding from the mouth reaching down to the chin, looking as if constricted by the lips. Generally red, epithelium off at the apex and under surface, edges blackened with dirty-looking matter, upper surface presenting much enlarged papillæ here and there with excoriations; under surface presents transverse ulceration owing to the irritation of the teeth in the lower jaw. It measures four and a half inches from one corner to the other passing over the apex along the edges. Circumference at the mouth about four inches and eight lines. Manipulation gives him no pain, the tongue lying within the mouth only slightly congested, the secretion of saliva not so great as stated at its commencement. The child was utterly unable to masticate food so that he had to be fed with liquids and comminuted articles of food; the incisors of the lower jaw project outward, but the jaw is not deformed. All the other parts of the body apparently normal; urine normal. Operation was performed on October 21st, under the influence of chloroform, by Dr. Takaki. The protruding part of the organ was removed with incisions of Λ-shape, the legs directed forward and outward to the edges, while the apex was toward the base of the tongue. Bleeding checked with torsion and wounds sewn up with six sutures. In order to prevent the retraction of the tongue within the mouth, two tough silk threads were passed on each side of the organ, their ends being held by the assistants. After the operation, the two threads were kept fixed on each cheek with adhesive plaster, the object was to pull the organ out so as to make the removal of sutures easier. A mixture of tincture of opium three minims, simple syrup half a drachm, and two drachms of water, was ordered to be given three times a day.

On the 28th of October the tongue became clean. The last suture was removed, it was purposely kept so long from fear of the wound not being able to heal as in ordinary cases, because the tissues were hardened. The wound entirely healed up, the tongue now presenting a round apex lying within the cavity of the mouth. Discharged.

Microscopic examination of the removed part corresponded with the description given by Virchow and others.

Antiseptic Tooth-washes.—At a recent meeting of the Odontological Society of Pennsylvania LEFFMANN reported his experience as follows: Several formulæ for antiseptic tooth-washes have been offered as fulfilling the indications here referred to, and, with a view of testing the practical value of these, I made up two forms, and present them for consideration by the members. In my opinion, they are both rather too strong, and can only be used very much diluted with water. This will, of course, interfere greatly with their antiseptic effect. Besides this, they are necessarily retained in the mouth for a very short period, and even if we suppose that they penetrate into all parts of supportive structures, they do not remain long enough to do any good. I give herewith the two formulæ, both of which I have used, and find the first the most agreeable:

Thymol	4 grains.
Benzoic acid	45 "
Eucalyptol	220 "
Alcohol	3 fluidounces.
Oil of wintergreen	25 drops.

Use a teaspoonful in about three tablespoonfuls of water as a wash.

Thymol	20 grains.
Alcohol	1 fluidounce.
Glycerin	1 "
Water	Enough to make 1 pint.

Use as above.—*Dental Cosmos*, February, 1888.

A Case of Idiosyncrasy Regarding Antipyrin.—STURGE reports in the *British Medical Journal* of February 4, 1888, the following interesting case of idiosyncrasy with regard to antipyrin. A member of my family liable to migraine was attacked in the ordinary way a few days ago, and I administered for the first time a dose of five grains of antipyrin in powder, with the following curious result: Five minutes after taking it, the "deadly sickness" which was previously present seemed to give way, and an "expanding sensation" was felt, rising from the stomach upward. Almost immediately she sneezed violently for about twenty times running without pause. The face and eyes became deeply suffused; tears began to flow; quantities of mucus flowed from the nose; the breathing became hard and labored, accompanied by a feeling of suffocation; there was complete inability to lie down. A violent cough shortly came on, and large quantities of mucus were expectorated; at the same time there was very profuse sweating.

After these phenomena had lasted for about half an hour, intense itching was felt on the insides of both thighs, and on examination there was found a thick outcrop of urticaria, which soon extended on to the abdomen. There was also a strong coppery taste in the mouth—not continuing, but coming on in violent bouts—and an equally strong smell of the same metallic nature, also intermittent. There was loud singing in the ears, which felt intensely congested. The pulse was quick and very full.

After the symptoms had lasted about three-quarters of an hour from the commencement, they gradually disap-

peared, some tightness of the chest and running at the nose remaining for four or five hours longer. The sickness accompanying the migraine disappeared completely as soon as the drug had begun to work; the headache also disappeared for a time, but came back slightly about four hours afterward.

Saccharine and Chartreuse.—Petit proposes an elixir of saccharine and *la grande chartreuse*, as follows:

Chartreuse	ℿ 15.
Spts. of wine	℥ 2.

Dissolve in this mixture

Saccharine	grs. 45.
Sodium bicarbonate	grs. 25.

the whole to be filtered.—*Journal de Médecine*, February 12, 1888.

Collapse Following the Use of Cocaine.—Lobker is quoted by the *Deutsche medicinische Wochenschrift* of February 2, 1888, in his experience with five cases of severe collapse following the hypodermatic injection of a fresh five per cent. solution of cocaine beneath the periosteum of the jaw, to produce anæsthesia in minor operations, as the extraction of teeth. The quantity used was half the contents of a hypodermatic syringe. Two of the patients had valvular heart disease, and the others had some functional derangement of the sympathetic nerves. Amyl nitrite was useless as an antidote, the patients recovering spontaneously after half an hour or an hour and a half. He advises greater care in dosage, and the use of carbolic acid as a local anæsthetic when possible.

A Simple Cure for Obstinate Hiccough.—Dresch, in the *Bulletin général de Thérapeutique* of January 30, 1888, writes that if the external auditory meati be closed by the finger-tips, and any convenient liquid be swallowed at the time in several deglutitions, obstinate hiccough will cease.

A Remarkable Aneurism.—The Vienna correspondent of the *Medical Press* of February 1, 1888, reports that Dr. Hochenegg, Assistant to Prof. Albert, gave, before the Imperial and Royal Society of Physicians, recently, an account of a case which had special interest, not only on account of the rare malady which had been observed in it, but also because it had given origin to a diagnostic mistake. A man, æt. twenty-one, was admitted into the hospital with an abscess in the region of the left elbow-joint. The patient had, when seventeen years old, suffered from rheumatism, and acquired thus an incompetence of the mitral valve. On careful examination, a painful tumor which pulsated was found to be present in the left elbow-joint. It was therefore assumed that they had to deal with an aneurism of the ulnar artery. After temporary strappings with an Esmarch bandage and digital compression, it seemed that the aneurism underwent a spontaneous retrogressive metamorphosis, when a new pulsating tumor became visible on the left retro-malleolar region, over which the skin presented the appearance of phlegmonous inflammation. The patient suddenly died (and as it became evident at the post-mortem examination) from the bursting of an aortic aneurism. The aneurism in the pit of the elbow did not derive its origin from the ulnar artery, but in the "arteria interossea." Dr. Paltauf, Assistant to Prof. Kundrat, in the chair of pathological anatomy, illustrated this case from the etiological point of view. Several observations had already been made on this disease, and Eppinger had described seven such cases which had been observed by himself, in all of which it had been the question of multiple aneurism in the largest part of the organs, besides relapsing "endocarditis verrucosa and bacteritia" of old date. The aneurisms had, with predilection, their site in those parts in which the arteries became divided, and, according to Eppinger, they were due to local inflammation of the wall of the bloodvessels, produced by emboli from the inflamed endocardium. Also Dr. Paltauf had, during last year, observed four similar cases, and so arrived at the same conclusions. The formation of the aneurism was preceded by an inflammation of the muscular coat of the bloodvessels, owing to which the "membrana elastica" and the "membrana intima" burst, and thus gave rise to the formation of aneurism. In the thrombi which have formed, vegetations of cocci could always be found in great quantities. The tendency toward relief could, in such cases, be the most easily explained by the inflammatory change of the wall of the bloodvessels, which thus favored the formation of thrombi. In some cases miliary aneurisms in the slightest arteries could be found in an immense number.

A Useful Emulsion of Copaiba.—The *American Druggist* for February, 1888, reports the following formula:

R.—Copaibæ	fl. ℥½.
Liq. potassæ	fl. ℥1.
Spir. æther. nit., Tinct. lavand. co., Syrupi	āā fl. ℥½.
Mucilag. dextrini	q. s. add fl. ℥4.

The Treatment of Chronic Pelvic Peritonitis by Chloride of Ammonium and Phosphate of Sodium.—Chéron has used, with good results, ammonium chloride by the mouth, as follows:

Ammon. chlorid.	1 part.
Syrup. simpl.	100 parts.—M.

Sig.—From one to five teaspoonfuls daily, after meals, in water.

In addition he has employed sodium phosphate, hypodermatically:

Sodii phosphat.	℥ 1½
Sodii sulphat.	℥ 1½
Aquæ destill.	℥ 30.

This solution should be freshly made, and carefully filtered.

This fluid he has injected slowly beneath the cellular tissue of the abdomen, where he has thought that he could locate inflammatory products. He also made gentle massage over the site of injection. This treatment was repeated in six or eight days.—*Revue gén. de Clin. et de Thér.*, January 26, 1888.

Menthol Cataract.—Roger and Charrin have recently observed, in animals poisoned by menthol the production of cataract. They have no explanation for the fact. It will be remembered that naphthaline has similar effects.—*Gazette Hebdomadaire*, January 27, 1888.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, MARCH 3, 1888.

ANTISEPTIC IRRIGATION OF JOINTS.

IN the treatment of effusions into the joints, an examination of our text-books shows that splints, rest, extension, compression, and revulsives are the agents mainly relied upon to effect a cure, followed, in cases of serous effusions, as a last resort, by puncture and the elastic bandage, and, in pyarthrosis, by incision and drainage.

In the *Centralblatt für Chirurgie* of December 8, 1877, Rinne describes antiseptic irrigation of the joints for these lesions, and illustrates his paper by nineteen examples of washing out the knee-joint with a three or five per cent. carbolic solution, derived from the practice of Schede. The operation consists, briefly, in evacuating, under strict aseptic precautions, with a trocar or aspirating needle, the contents of the joint, distending the latter with the solution for a few times, and then by rubbing, kneading, and alternate movements of flexion and extension, the joint being half filled, bringing the fluid in contact with every portion of the synovial membrane. The washing out is continued until the fluid returns clear; a splint and the usual outer dressings are applied for six or eight days; passive motion is then instituted until two weeks, as a rule, have expired, when the patient is discharged, but enjoined to wear a flannel bandage for a few weeks. If, on removing the dressings, there is a fresh effusion, complete rest with compression is kept up for several additional days before resorting to passive motion. The cases pursued, first, an afebrile or slightly febrile course, without relapse; secondly, a moderately acute inflammation was set up, resulting in fresh effusion, which, however, rapidly disappeared; and, thirdly, in old cases with thickening of the capsule and perisynovial tissues, and stretching of the ligaments, the effusion persisted, and the operation had to be repeated.

A study of the cases shows that this simple and absolutely safe procedure should replace the other more tedious, and frequently highly unsatisfactory, method in all examples of acute, subacute, and chronic synovitis, whether serous, serofibrinous, or purulent, as well as of acute hæmarthrosis, and of tubercular inflammation in its early stage.

The paper of Rinne appears to have been either overlooked, or to have been regarded with suspicion, since we do not find that primary antiseptic flushing of the joints is even referred to in our standard surgical text-books and manuals. This is to be the more regretted, as a more extended experience has fully confirmed the results attained by Schede, and demonstrated that the operation is as harmless as that of injecting a hydrocele, and that it may, in many instances, do away with incision and drainage.

In the *Deutsche Zeitschrift für Chirurgie*, Bd. xxvii., Hefte 1 and 2, HAGER presents a large array of cases, derived mainly from the General Hospital at Hamburg, which substantiate the statements made in the preceding paragraph. Taking the knee-joint as an illustration of the practice, we glean the following pregnant facts.

Of 100 examples of ordinary dropsy, all were cured, with the exception of one occurring in a tubercular subject, and in only 4 was a repetition of the operation required. In 25 cases of an acute character, as indicated by severe pain, great tension, and, in a few, by fever, and contraction of the muscles, the duration of treatment did not exceed two weeks. In the 75 subacute or chronic cases the average time required for a cure was somewhat longer, and the treatment was supplemented, when the capsule was much thickened, by douches and energetic massage. In 4 of these cases the patients were discharged with an immovable dressing, on account of lateral mobility of the joint and a tendency to genu valgum; while in 7 forced movements were required to restore proper function. The longest duration of treatment was seven weeks.

In the 9 cases of acute and 1 of chronic hæmarthrosis, the latter being a bleeder, washing out the fluid resulted in excellent recoveries.

The operation was practised in 15 cases for suppuration. Of these 2 occurred in pregnant women, and motion was perfect; 3 resulted from rheumatism, of which 1 recovered with normal, and 2 with almost normal, movements; and 10 were due to epiphyseal osteomyelitis, of which 3 had limited motion, and 7 had ankylosis.

Fourteen joints were punctured and irrigated for tubercular inflammation. One patient recovered with normal motion, but partial ankylosis resulted in the remainder.

In addition to these examples of effusion into the knee, the statistics include many other cases in which the knee and other joints were affected, and in which the results cannot be separated. Thus, of 8 instances of acute primary suppuration of the knee and 4 of the elbow, 4 were discharged with normal joints, 2 in immovable dressings, 1 with ankylosis, and 1, a drunkard, died of delirium tremens, after incision and drainage. In 4 examples of suppuration following infectious diseases, the result was perfect in all, the knee having been affected in 2 cases, the elbow in 1, and the shoulder in 1. Of 15 cases of gonorrhœal inflammation, the joints involved being the knee in 9, in 5 of which the fluid was purulent, elbow in 2, wrist in 2, hip in 1, and shoulder in 1, motion was normal in 7, almost complete in 5, limited in 2, and abolished in 1. Finally, of the 12 cases of rheumatic synovitis, the knee being involved in 11, and the elbow in 1, motion was perfect in 9, and almost perfect in 3.

A review of the foregoing facts shows that of 168 cases of antiseptic flushing of the knee, all recovered, and that of 30 examples of purulent effusion, in only 1 did the procedure fail, thereby demonstrating that it should be employed before resorting to incision with drainage. These results are so brilliant that it is to be hoped that the treatment will be fully tested. It may be added that, in the infectious inflammations, including the gonorrhœal, a one to one thousand solution of sublimate is to be preferred to the carbolic solution.

THE USE OF METHYLAL IN DELIRIUM TREMENS.

In the *Therapeutische Monatshefte* for February, 1888, Krafft-Ebing, of Graz, gives brief clinical histories of twenty-one cases in which he obtained quite remarkable results from the use of methylal in delirium tremens, and nearly all of them were discharged in from two to four days entirely well. The sleeplessness, which was naturally the most prominent symptom in nearly every case, aside from the other cerebral disturbances, yielded with remarkable rapidity to the drug, and, along with the banishment of the insomnia, the terrors and nervous excitement were relieved. In every case he used the drug hypodermatically, in the dose of from seven and a half to fifteen grains dissolved in distilled water.

On the other hand, the conclusions of Mairet and Combemale are by no means so favorable, for they found that at the outset of acute mania, doses of as much as a drachm and a half or two drachms failed to quiet the patient, but later on succeeded. In the three cases in which alcoholic mania existed, the results were entirely negative. Further than this, they conclude that the drug, to be of any use, must be given in constantly increasing doses. It is proper to state, however, that Mairet and Combemale gave the drug by the stomach.

Krafft-Ebing was often forced to repeat the hypodermatic dose of the drug within a short time, but a single repetition was generally all that was needed. As the latter writer has had a much wider opportunity for using methylal than his French brethren, and as his results were so uniformly good, the drug is at least well worth trial in this class of cases by our readers.

It will be remembered that methylal is a pure somnifacient, and that it causes no secondary depression, as do morphia and chloral. When given in very large doses, it probably kills by both respiratory and cardiac failure; and very large doses are apparently necessary to cause death.

The larger doses had better not be given hypodermatically, since great pain, and even sloughs, may result. This is evidently one of the reasons for the small doses used by Krafft-Ebing.

The story of the chrome yellow bun poisoning cases in Philadelphia is familiar to our readers through the able clinical study by Dr. David D. Stewart, which appeared in our columns last year. The Court has just tried some of the bakers, and has imposed sentences varying from six to nine months' imprisonment upon the defendants who had used chromate of lead to give an attractive color to their cakes and buns. In view of the fact that they had already suffered severely in the loss of business, and one of them in the death of his own children and in his own impaired health, and also in view of their probable ignorance of the very poisonous nature of the adulterant, the Court tem-

pered its justice with mercy. The parties who prepare and put upon the market these poisonous adulterations must, however, know full well their toxic character, and it is to be hoped that the law will hold them to a rigid accountability.

THE Loomis Laboratory of the University of the City of New York was opened for inspection by the public, on last Monday evening. The Laboratory building, situated at 410 East Twenty-sixth Street, occupies a lot thirty-five by ninety feet, and is five stories in height. The first story is devoted to physics and materia medica, the second to chemistry, the third to physiology and histology, the fourth to pathology, and the fifth to bacteriology. In addition to the facilities for the instruction of undergraduates, every convenience will be afforded to those who are interested in scientific medicine to prosecute their studies and researches. It is reported that the anonymous donor of the Laboratory proposes to endow it with a sufficient income to cover the expense of its maintenance.

THE Court of Claims, last Monday, overruled the action of the accounting officers of the Treasury in disallowing the claim of Surgeon John S. Billings, U. S. A., for mileage, while travelling in Europe under orders of the Secretary of War. The claim was for about $1500, and was disallowed on the ground that there was no legal authority for the expense. The Court held that the Secretary of War had ample authority in the premises, and that the accounting officers had no right to interfere. Judgment was given in favor of the claimant for the full amount.

AT a recent meeting of the Society of Physicians of Vienna, von Bamberger announced the payment to the Society of 12,000 florins, the legacy of the late Dr. Da Costa Alvarenga, of Lisbon. It will be remembered that the same generous donor left similar bequests to the Berlin Medical Society, and to the College of Physicians of Philadelphia. The latter society has, also, we are informed, received its legacy, amounting to over $4100.

ALTHOUGH not prevalent, except in California, this seems to be a year of wide distribution of smallpox, the disease having been reported, since January 1, 1888, in Connecticut, New York, Delaware, Ohio, Indiana, Michigan, Wisconsin, Iowa, six places in California, Tennessee, and Louisiana. Vaccination and revaccination are preventives of smallpox, and if people keep thoroughly protected in this way, no epidemic of the disease can occur. Now is the time for those who have not been vaccinated or revaccinated within the last five years to take this precaution.

THE Fourth International Otological Congress will be held in Brussels, Belgium, from September 10 to 16, 1888, immediately after the meeting of the German naturalists and physicians in Cologne, Germany.

AMONG the forty-two foreigners who received the title of Doctor of Medicine in Paris during the past year were seven Americans. The degree was given to four women, two of whom were Americans.

The number of medical students of all nationalities in Paris during the year was between 3000 and 4000. Next on the Continent comes Vienna, with 2178; Munich, 1211, and Berlin, 1140.

THE Seventh Congress of the German Society for Internal Medicine will be held at Wiesbaden, April 9–12, 1888, under the presidency of Leube.

We are requested by Dr. Pfeiffer, Permanent Secretary of the Congress, to announce the following subjects and the names of those who will preside over their discussion :

Chronic Diseases of the Heart Muscle, and their Treatment, Oertel and Lichtheim; Alcohol as a Therapeutic Agent, Binz and von Jaksch ; The Prevention and Treatment of Cholera, Cantani and Pfeiffer.

Contributions are also announced from Rumpf, on Dislocated (Wandering) Heart ; Unverricht, on Experiments on Respiratory Mechanism ; Liebreich, subject not yet announced ; Adam Kiewicz, on Multiple Degeneration of the Spinal Cord ; Jaworski, on The Dietetics of Dyspepsia ; Stiller, Treatment of Basedow's Disease and the Diagnosis of Kidney Tumors ; Pfeiffer, on Urinary Secretion and the Solution of Uric Acid ; Binswanger, The Pathogenesis of Epilepsy ; Jürgensen, Cryptogenetic Septic Pyæmia.

THE Alumni Association of the Long Island College Hospital held its annual meeting on the 27th ult., when it was addressed by Dr. Abraham Jacobi, in a lecture upon the heart and bloodvessels of the young.

REVIEWS.

Rectal and Anal Surgery, with a Description of the Secret Methods of the Itinerants. By Edmund Andrews, M.D., LL.D., Professor of Clinical Surgery in the Chicago Medical College, and E. Wyllys Andrews, A.M., M.D., Surgeon to Mercy Hospital. 8vo. pp. x. 111. Chicago: W. T. Keener, 1888.

The chief object in writing this book would appear to have been the desire to animadvert upon those peripatetic quacks who find ample reward in storming the breaches of credulous humanity. Its authors have been at the pains of examining into the secret methods of these gentlemen and mercilessly and most properly expose the very slender scientific basis upon which their treatment rests. In so doing they have supplied information which would otherwise have been inaccessible to very many of the profession.

But while the subject to which we have referred seems to be the chief one the Doctors Andrews have had in view, it is not so ostensibly, but comes out in the course of chapters which systematically treat of some diseases of the rectum. The advice contained in these chapters is always sound, although we fail to find anything particularly new or fresh in the book; it is profusely supplied with illustrations, those taken from Esmarch's work being valuable.

The Efficacy of Coca Erythroxylon. Notes and Comments by Prominent Physicians. 12mo. pp. 61. New York, 1888.

In this little volume, which is issued as a supplement to his "Treatise on Coca," M. Mariani has gathered the testimony of a large number of the profession in various parts of the United States as to the therapeutic value of the preparation of the wine of coca known as "Vin Mariani." One of the secrets of the admirable character of this tonic is, that it is made with a pure, fine quality of grape wine, of M. Mariani's own production, which blends admirably with the fresh selected coca leaves, which alone are used. This brochure, we are informed, will be forwarded to any physician upon application to Mariani & Co., New York.

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, February 8, 1888.

The President, J. Solis-Cohen, M.D., in the Chair.

Dr. Mordecai Price reported

A CASE OF NEPHRECTOMY FOR GUNSHOT WOUNDS.

Maggie McG., of Avondale, Chester County, Pennsylvania, aged fourteen years, white, pale, anæmic girl, was accidentally shot on Wednesday, December 21, 1887, at 8 o'clock in the morning, while handling a four-barreled Sharp's pistol, 30 calibre. She had the muzzle of the pistol turned toward the right side; while attempting to raise the lock with the thumb of her left hand it slipped from her hold and fired the cartridge, which entered her body at the junction of the ninth rib with the cartilage, passed directly through the left lobe of the liver, entered the upper third of the kidney, and passing through lodged in the deep muscles of the back near the spine. When he first saw her—twenty-four hours after the accident—her condition was an exceedingly alarming one: pulse 150; temperature 103°. She had passed, soon after the accident, a large quantity of blood from the bladder. But at the time Dr. Price saw her she was not passing blood from the bladder, showing that if there was still hemorrhage it was into the peritoneal cavity, and also that the bladder was not wounded, for the urine was normal.

Symptoms of peritonitis were well marked; abdomen considerably distended. He had no difficulty in coming to a conclusion as to what was best to be done. Dr. Charles Penrose and himself at once advised the removal of the kidney. This was concurred in by Dr. Hudders and Dr. Ewing, the attending physicians. The patient was etherized and the abdomen opened. A large quantity of clotted blood was removed from the abdomen, the wound of the liver was examined, both entrance and exit. No hemorrhage was found coming from it. The abdominal incision was then enlarged, and the blood removed from the region of the right kidney, when it was plainly seen that the hemorrhage was from that organ. The kidney was examined and found to have a hole in its upper third, large enough for a finger to enter. He then made a button-hole opening through the peritoneum with scissors, introduced the finger and enlarged the opening by tearing, and without much difficulty enucleated the kidney from its bed. The ascending colon was pushed back or inward toward the spine, and the opening in the peritoneum, through which the kidney was removed, was made in such a manner that the vessels of the bowel were not disturbed. The ligaturing of the pedicle was exceedingly difficult, Dr. Penrose having to tie the ligature the full length of his hand in the peritoneal cavity. Two ligatures were applied, one through the pedicle tying it in halves, the other, a large, heavy ligature with one knot; then the kidney was cut away and the ligature tightened before making the second knot. The stump of the pedicle, or button, as it is called, to keep the ligature from slipping, had a portion of kidney structure in it. There was complete irrigation. A glass drainage tube was left in the kidney wound and the abdomen closed. The patient rallied nicely from the ether, and, on the morning of the second day, Epsom salts was given in large and repeated doses, but could not be retained. On the morning of the third day, a second attempt was made to have her bowels moved. Rochelle salts was used, followed by two or three evacuations and passage of flatus by the bowels, which gave great relief. Patient did uninterruptedly well, with temperature not over 102° up to the time (eighth day) of the removal of the glass drainage tube, when rubber drainage was substituted, and was left too long, producing quite a rise of temperature and fetid pus at the bottom of the tube, which was at once relieved by the attending physicians removing the tube and cleaning the drainage track.

On January 4th Dr. Price was telegraphed for, patient's temperature having been up to 103° the previous night. Abscess was suspected either in the liver or the muscles of the back. He met Dr. Hudders and Dr. Ewing, her attending physicians, in consultation, and found no positive indication of abscess—the girl being in a[mode-

rately good condition at the time, with a slight tendency to diarrhœa—temperature 100 4/10°; pulse 100. She continued to do well until the 11th of January, when Dr. Ewing wrote him. "Some new trouble seems to be developing in our patient, her temperature is 103 3/0°, her liver is enlarged and tender; complains of pains in left side and shoulder." On the 12th there was quite a gush of pus and bile from the drainage tube opening—about two ounces—this at once relieved her of high temperature and quick pulse. She has had many changes in the last three weeks, with slight discharge of bile and pus from the drainage tube, but has constantly, but very slowly improved. Her physicians have given her every attention, and to them he was greatly indebted for the care they have given her; nothing but their interest in the case could compensate them for their labors. For the result in this case he is also greatly indebted to Dr. Charles Penrose, for assistance rendered during the operation. Length of incision six inches. Kidney removed for hemorrhage.

DR. EWING, of West Grove, had nothing to add, except that the condition of the patient is better than Dr. Price states. At the last dressing there was only a drachm of pus discharged. There is refreshing sleep; temperature is normal in the mornings, though there is a slight evening rise; appetite is good; the bowels are regular. He felt that recovery is assured. This child was on the verge of death when the operation was done—the pulse was 150; temperature 103°; the extremities were cold; the body covered with clammy perspiration. Improvement was manifest at once.

DR. J. B. ROBERTS said that while he could not speak from experience, it has occurred to him, and the same suggestion has been made by others, that the difficulty of tying the stump so far down, and behind the peritoneum, might be lessened by getting the kidney enucleated and then twisting it so as to apply torsion to all the renal vessels, veins as well as arteries. Afterward the ligature might be applied with more ease, and this whether abdominal or lumbar incision be made, though in the absence of experience he judged that it would be easier to do this with a lumbar incision. He presumed that there was no intestinal wound in this case, no mention having been made of any.

In connection with the operation by lumbar incision, he might refer to an error of his own, which illustrates the mistakes our lack of familiarity with operations in this region may lead us into. The operation was undertaken for a supposed stone in the kidney; but as no stone was found, it resolved itself into an exploratory incision and acupuncture of the kidney. The ordinary lumbar incision had been made with care, and he had come upon the kidney with ease. It was suggested that he should enlarge the wound upward and explore the upper end. A few muscular fibres stretched across the upper angle of the wound, and these he divided by a small cut, when a rush of air into the pleural cavity informed him that he had cut a small hole in the diaphragm. The accident did no harm; it was easily remedied with a few sutures; and the dyspnœa that persisted for a few days was attributed by the patient to the tightness of the abdominal bandage. He was not sufficiently familiar with operations in this region to realize to what extent the posterior attachment of the diaphragm to the vertebræ dips down here, especially when he saw, as he did, the main mass of the diaphragm bulging down as a great sheet in front of the point where he made the additional incision.

The PRESIDENT asked how Dr. Price accounted for the bile.

DR. PRICE could not say where the bile comes from, unless from the liver. The wound in the liver is about two inches from the gall-bladder. The ball took a diagonal course and came out at the margin of the liver, and then entered the kidney. He did not know what the effect of twisting the pedicle would be. He could bring the edge of the kidney within an inch of the wound. He considered the abdominal incision the proper one. In this case there were several considerations in its favor. Hemorrhage had already taken place into the peritoneal cavity; it gave the chance to examine for wounds of the liver and intestines. He found only wounds of the liver and kidney. The liver was not bleeding, and he had only the kidney to deal with. In view of the discharge of pus from the liver, he now believes that it would have been better to insert into the track of the bullet in the liver a small glass drainage tube—that of Bantock, which is of about the same diameter as the ball—and drained it. If, as has been stated to him by Dr. Wood, there has been no case of recovery from bullet-wound of the liver, we are not going to make the prognosis any worse by draining, and he thought we might make it better.

DR. FRANK WOODBURY, in connection with the case reported, briefly related the notes of

A CASE OF NEPHRECTOMY FOR PYONEPHROSIS,

performed for him by Drs. Deaver and Agnew, last year, at the German Hospital:

The woman first came to him in the spring of 1886, for vesical irritation, with bloody urine. She had had several such attacks following exposure to cold and wet some two years previously. In September of the same year there was another attack. The urine contained pus, but no blood. He washed the bladder with boric acid and alkalies, and subsequently with a weak solution of nitrate of silver. The pus continued, epithelial tube-casts appeared, and a tumor slowly developed in the right side. Dr. Deaver saw the case in consultation and concurred in the diagnosis of pyonephrosis of right side consecutive to inflammation of the bladder. Dr. Agnew saw the case on December 25th, and agreed in recommending operation. On January 10, 1887, nephrectomy was carefully and skilfully done by Drs. Deaver and Agnew. Death occurred five days later, from exhaustion.

DR. DEAVER said that the steps of the operation were lumbar incision, which exposed the kidney closely adherent to all parts, especially to the under surface of the liver and to the iliac vessels. It was distended with pus, six ounces being evacuated prior to its removal. The mass was very large, and to deliver it without wounding the peritoneum required great care. He now regretted that he extirpated, as he believed it would have been better surgery to incise the kidney, wash out the abscess cavity, insert a drainage tube, and to dress it antiseptically as in nephro-lithotomy.

Much difficulty was experienced in ligaturing the pedicle, as in Dr. Price's case. He believed the abdominal incision to be preferable in dealing with greatly enlarged kidneys. In performing the abdominal operation,

the mesocolon descending, instead of the internal mesocolon, which carries all the bloodvessels, should be divided, thus avoiding the danger of gangrene of the gut. Delivery is easier, and better access is given to the adhesions, especially those to the iliac vessels.

Dr. J. B. Roberts said that the case of Dr. Woodbury suggests some studies he made and reported to the American Surgical Association a few years ago. Something can be gained in the way of diagnosis in the early stages of perinephritic abscess and other lesions in this region by the study of certain trains of symptoms, pointing to the localization of the disease. Inflammatory affections about the upper end of the kidney, for example, will often show on careful examination a limited pleuritis; when the lower part is involved, there is apt to be spasm of the psoas muscle with flexion of the thigh; in the middle part, pressure on the renal vein and other vessels may cause an otherwise inexplicable albuminuria.

Dr. Penrose reported a case of

OBSTRUCTION OF THE BOWEL BY CANCEROUS MASS; OPERATION; WITH FORMATION OF ARTIFICIAL ANUS.

The operation was performed seven days ago. There had been complete obstruction of the bowel for twenty-eight days prior to operation. Fecal vomiting occurred two days before operation. At time of operation there was immense abdominal distention, a temperature of 101°, and a pulse of 150. An abdominal incision four inches in length was made, revealing complete occlusion of the descending colon by a cancerous mass twelve inches long, involving also the meso-colon.

Resection was made of the gut and meso-colon, and all indurated tissues were removed. The two ends of the divided gut were brought together laterally and united to each other, and the long axis of the abdominal incision, with continued suture, so as to make an artificial anus. A bucketful of fluid feces was discharged immediately after the operation. Relief was immediate; quiet sleep lasted for thirty-six hours. At present the abdomen is flat; the pulse is 80 to 90; temperature 99°; there is no pain; the tongue is clean; appetite good, and the patient doing remarkably well.

NEW YORK ACADEMY OF MEDICINE.

Section on Obstetrics and Gynecology.

Joseph E. Janvrin, M.D., Chairman.

Stated Meeting, February 23, 1888.

Dr. H. J. Garrigues read a

REPORT OF CASES OF LAPAROTOMY FOR RUPTURED UTERUS.

(See page 225.)

Dr. Robert A. Murray read a paper on

THE INDICATIONS FOR THE USE OF THE INTRA-UTERINE DOUCHE AFTER PARTURITION.

He commenced by giving a report of a case which he was summoned to see in consultation in a neighboring city, in which there was a febrile condition, believed by the physician in charge to be of malarial origin. He found the patient almost in a state of collapse. The temperature was 104½°, the pulse 130, the face pinched, and the lochia scanty and fetid. There were intense headache, considerable abdominal pain, marked tympanites, and a tendency to delirium. On making an examination he ascertained that there were septic endometritis and peritonitis present. The vulva was swollen, the cervix uteri badly lacerated, and the perineum partially ruptured; and in the interior of the uterus he found portions of the placenta adherent. Against the advice of the attending physician he made first a vaginal injection, and then removed the adherent placenta, and used the intra-uterine douche. This was followed by an almost immediate reduction of the temperature. Reaction was slight, and in four weeks the patient was restored to health. The physician thought that the powers of nature were sufficient to deal with the retained placenta; but Dr. Murray felt confident that if this had not been removed, and the mode of procedure mentioned not adopted, the patient would undoubtedly have succumbed to the septicæmia from which she was suffering when he was called in. He said that he mentioned the case as an illustration of the prejudice that still existed in the minds of many medical men against the use of the intra-uterine douche.

He then went on to speak of the indications for the employment of this measure, and first in the way of prophylaxis. Even in cases of non-instrumental labor it is sometimes called for if the labor has been tedious. Such long labors are frequently followed by fever, and if the os is found to be patulous, and the finger after being withdrawn from the uterus has a necrotic odor, even although no remains of placenta or membranes, or no clots can be detected, the use of the intra-uterine douche is indicated at least once. It not only has the effect of closing the vessels by the stimulating effect of the hot water employed, but also prevents septic absorption. It should also be resorted to when instruments have been used, or the hand introduced into the uterus for turning, etc., in cases of placenta prævia, and in rupture of the uterus. Also in those cases in which the patient has a chill during confinement; this chill being the precursor of fever.

In the treatment of many cases of puerperal fever it constitutes the most valuable agency at the command of the accoucheur. All cases of fever depend on septic absorption, and the uterus should be thoroughly explored for clots or adherent tufts of placenta. Especially should such exploration be made if the lochia are fetid. In many cases, however, there is no fetor about them, owing, no doubt, to the effect of the antiseptics used. In all such cases a careful examination of the uterine cavity should be made, in order to show that no source of sepsis remains within it. In the treatment of abortion, and after the induction of premature labor, the intra-uterine douche is also often of much service.

The only articles needed for carrying out the treatment are a fountain syringe with a long rubber tube attached, one intra-uterine glass tube (the Chamberlain tube is the one preferred by Dr. Murray), a rubber blanket, a thermometer to gauge the temperature of the water, a rubber cloth to protect the bed, etc., a Thomas blunt curette, and a placenta forceps, the Simpson forceps being the one preferred. The patient is gently moved (not lifted) to the side or foot of the bed, and placed in the lithotomy position, with the rubber cloth around her waist, and a blanket over her. The intra-uterine tube is guided by two fingers, and the vagina first washed out. When the cavity of the uterus is injected an assistant should

keep the organ contracted with his hand, but should be careful not to press the organ downward. The flow is to be continued until the returning fluid is entirely devoid of odor or color. The solutions which Dr. Murray generally employs are carbolic acid, 2 to 100, or bichloride of mercury, 1 to 3000 or 5000.

He next spoke of some of the objections which have been urged against the use of the intra-uterine douche, such as the danger of causing shock and collapse, peritonitis, hemorrhage, the formation of clots, and resulting embolism, of wounding the endometrium, of introducing septic matter into the uterus, of the entrance of air into veins, and of poisoning the general system by the absorption of the antiseptics used. The endometrium, he said, will not be wounded if the douche is properly managed; and shock, collapse, and peritonitis may be avoided if the uterus is firmly grasped by the assistant. The majority, if not all, of the cases of this kind reported have been those in which iron has been used as the styptic. Entrance of air into the veins can be prevented by keeping a continuous flow from the syringe, and the hot water of the douche itself acts as a strong preventive of hemorrhage by exciting uterine contractions. Dr. Murray also recommends that ergot should be administered after the douche, by way of precaution against hemorrhage.

The intrauterine douche is by no means to be employed in every case of midwifery, but only in the limited number embraced in the class of cases above referred to. Finally, the physician should always administer the douche himself, and never permit it to be given by the nurse.

DR. ANDREW F. CURRIER said that he thought none of those present would deny that the development of the antiseptic theory has forever done away with the idea that nature will successfully take care of those cases of sepsis arising from retained portions of the placenta, membranes, etc. At the same time experience has taught us the necessity of proceeding with great caution in such cases, and the applications required should be made in such a way that the danger of the procedure may be almost wholly removed.

Dr. Currier said that, in general, his rule is to use a vaginal douche if the uterus contracts readily, and then to apply a Garrigues antiseptic pad, which he has usually found to act very satisfactorily. If afterward, however, a high temperature, and other indications of sepsis show themselves, he resorts to the intra-uterine douche. He had found the Chamberlain tube excellent, and the only improvement that he had to suggest in regard to it was that it should be made of some flexible material, instead of glass. In some of the more serious cases he would advise that the tube should be allowed to remain in the uterine cavity until all evidences of sepsis have passed away, as it affords a valuable means of drainage. In a case of retained menses, in which the Chairman of the Section, Dr. Janvrin, was called in consultation, this plan had been pursued with excellent results. It is much more convenient simply to adjust the rubber tubing to the intra-uterine tube from time to time, than to have to reintroduce the latter. He has also found this method of great value in some cases of abortion.

DR. H. J. BOLDT spoke of the position of the patient during the administration of the douche. While that recommended by Dr. Murray is entirely unobjectionable if but a single injection is to be given, he thought that if the douche is to be repeated, some other is preferable. His method is to allow the patient to remain in the ordinary position on the back in bed, and to place under her an ordinary bed-pan or a douche pan. The rubber tube is passed through the handle of the bed-pan, and instead of the Chamberlain intra-uterine tube he employs a gutta-percha male catheter of large size, to which the rubber tubing is attached. By this means constant irrigation of the cavity of the uterus can be maintained as long as is desired. Dr. Boldt does not use either carbolic acid or bichloride solution, but simply hot water, of a temperature of 110° or 112°, and he thinks this decidedly preferable for constant irrigation. Such irrigation has this advantage, that it can be carried on for an indefinite period without the presence of the physician being necessary after the douche is once commenced.

He then went on to say that he employs the intra-uterine douche in every case in which he is called in consultation where he finds that the attending physician has made use of no antiseptic precautions during the labor, and in such cases, where only one injection is made, he prefers bichloride of mercury solution as the fluid. It was surprising, he thought, that notwithstanding all that has been said and written of the advantage of antiseptics in midwifery practice, so many physicians still persist in attending their confinement cases without employing them, even when instrumental delivery or operative procedures are resorted to.

DR. MALCOLM MCLEAN called attention to what he considered a serious defect in many of the Chamberlain tubes that are sold in the shops, viz., that the orifices for the passage of the fluid injected extend for a distance of six inches or more from the extremity of the tube. When this is the case a considerable portion of the fluid is apt to escape into the vagina, and the results are very unsatisfactory. It is important to see, therefore, that the holes are all within two inches of the extremity of the tube.

DR. A. PALMER DUDLEY spoke of the value of ergot in the prevention of sepsis, and said that he thought Dr. Murray made a mistake in postponing its administration until after the use of the intra-uterine douche, sepsis having already occurred, instead of giving it before any such condition had arisen. Dr. Murray had referred to the necessity of making pressure upon the uterus to prevent distention of the organ while the injection was being made; but he believed that if the uterus from the first was properly contracted there was very little danger of sepsis. He always made it a routine practice to administer one or two drachms of the fluid extract of ergot after the birth of the child in every case of midwifery that he attended.

In regard to antiseptics Dr. Dudley said that he did not now have as high an opinion of their value as formerly, and it is a fact that many of those who practise abdominal surgery have entirely discarded them, and yet have as good results as their confrères who still employ them. In the intra-uterine douche he believed that boiled water of a temperature of 110° is all that is necessary. Both carbolic acid and bichloride solutions, if used in sufficient strength to be of any value as germicides, are irritants, and he thought that we are coming to realize that if we exercise proper care in our cases, and do not bring dirty hands or dirty instruments

in contact with the patient, there will be very little use for the intra-uterine douche.

Dr. Garrigues said that in most points he was in entire accord with the author of the paper. After a very considerable experience with both carbolic acid and bichloride of mercury, he very decidedly preferred the latter as an antiseptic. As to the danger of poisoning by the chloride, he had never met with a single case in which there was any untoward result from its use, and he believed that in the cases of poisoning reported by others, either a very strong bichloride solution or an immense quantity of fluid was employed. He is in the habit of using a solution of the strength of 1 to 4000, but one even so weak as 1 to 10,000 has very decided germicidal properties. As a rule, it is advisable to use a rather stronger solution in hospital than in private practice. He did not think there is the slightest danger attending the employment of the bichloride, provided that a strength of 1 to 4000 is not exceeded and that too large a quantity of the solution is not used. The amount should never be greater than three pints, and in the majority of instances one quart is sufficient.

He had found that it is not necessary to repeat the douche so often if after giving the injection an iodoform pencil containing ninety grains of the drug is inserted into the uterus, and since using such pencils he had found that only one douche is required in the twenty-four hours. It is important that the patient should always be on the back when the douche is used, since if she lies upon the side there is danger that some of the fluid may by means of a dilated Fallopian tube get into the peritoneal cavity. In order to get rid of the superfluous amount of bichloride solution the uterus ought always to be squeezed after the injection has been made. It is not necessary that the intra-uterine douche should be resorted to in every case of fetid lochia, as it may be found on examination that the source of the fetid condition is in the vagina.

Dr. Paul F. Mundé said that for some years past he had had very decided convictions as to the circumstances in which the intra-uterine douche should and should not be employed. If, on being called to any puerperal case in which there was an offensive discharge associated with a rise in temperature, he was not satisfied with inspecting the vulva and vagina, but proceeded to insert his finger into the uterus, when he was almost sure to find a portion of retained placenta or some putrid blood-clots, he removed these with the finger or blunt curette, and then thoroughly scraped the uterine walls; after which he proceeded to irrigate the cavity. For this purpose he uses either the Chamberlain glass tube, large or small size, or, what is perhaps better, the recurrent catheter of Fritsch, and the fluid that he injects through it is either lukewarm carbolic acid solution, one to two per cent., or simple warm water.

Bichloride of mercury solution, in any strength, except so weak as to be of mythical value, Dr. Mundé considered entirely inadmissible, on account of the risk involved. The number of deaths by mercurial poisoning from the use of the bichloride in this way has now become so large that the danger can no longer be disregarded. Only recently a case has been reported in Germany in which a fatal result has occurred from the use, but once or twice, of an intra-uterine injection of a bichloride solution of the strength of 1 to 4000. Furthermore, he did not believe that such a solution within the uterus is of any antiseptic value whatever. By the time that it comes in contact with the uterine walls septic matter has already been absorbed, and the process of infection has gone too far to be interfered with by any such local application.

If nothing is found in the uterus on exploring its cavity with the finger, it is well to give a single intra-uterine douche; but it is useless, and may give rise to serious trouble, to go on with the douche afteward in such cases. If there is a hemorrhagic tendency, Dr. Mundé is in the habit of employing an injection of equal parts of hot vinegar and water; and after any injection he always squeezes the uterus dry in order to secure proper contraction of the organ. He then spoke of the danger of causing signs of collapse by repeating the douche, and said that if there were no indications of its repetition, this should by all means be avoided. There is also the possible danger of injecting air into the veins. He had seen the use of the douche persisted in even in cases where there was such trouble as localized peritonitis or cellulitis, which constitute a positive contra-indication to this measure. The mere rise of temperature or the occurrence of fetid lochia is not, as a rule, sufficient to call for the intra-uterine douche, but if both these conditions are present, it should be given at least once. In conclusion, Dr. Mundé said that he could not see any possible advantage in the iodoform pencils advocated by Dr. Garrigues, and especially since it is somewhat problematical in the light of recent investigations whether iodoform is an antiseptic agent at all.

Dr. Murray, in closing the discussion, said that the dangers referred to by Dr. Mundé are principally liable to be met with where the intra-uterine injections are made late. He believed with him that the diagnosis should always be made, if possible, with the finger; but if on withdrawing the finger it is found to have a necrotic odor, indicating dead tissue, even though no clots or remains of placenta or membranes can be detected, he thought that the intra-uterine douche should be resorted to. A patulous condition of the os and a necrotic odor may, in general, be stated to constitute the indications for the injection.

He doubted whether hot water alone is sufficient. He believed in the cleansing properties of antiseptics; but, more than that, they destroy tissue which left undisturbed would become septic. It is in this way that they tend to prevent further absorption of septic material in cases where the system has already, to some extent, become infected. In his opinion, therefore, the use of the bichloride of mercury is sometimes essential.

In regard to ergot, Dr. Murray said that, like Dr. Dudley, he gives it as a routine practice in every case of midwifery that he attends; but the closing of the mouths of the uterine vessels, just after the birth of the child, will not prevent their relaxing afterward.

CORRESPONDENCE.

PRESERVATION OF SEVERED DIGITS.

To the Editor of The Medical News,

Sir: Under this caption Dr. W. A. Miner (*The International Journal of Surgery and Antiseptics*) calls attention to the importance of the preservation of crushed or severed digits. "Since it is the routine practice of many doctors to snip off a partially severed finger, or

remove one if badly crushed, without making an effort to save it, any facts that will aid us in our attempts to prevent such a loss should be carefully studied. Especially is this the case since there have been published within a year, some half dozen cases of digits severed and afterward reunited. That there have been some failures, counts for nothing. There have certainly been no reports of any unpleasant results following the attempt. The public, too, are beginning to realize that the useful little member is sometimes needlessly sacrificed. Another case can be added to those already published which presents one unusual feature—the long time that elapsed before the severed end was adjusted to the stump." "A boy while splitting wood, cut off part of his right thumb. It dropped to the ground and he ran into the house. The mother hunted up the father, who came to the barn, harnessed the horses, wrapped the piece of thumb and the stump up in a rag, and drove nearly three miles to the doctor. Fully an hour and a half elapsed before I saw him. I removed the bandage and found the thumb lying loosely in the bandage and covered with sand and dirt. I washed it off and secured it to the stump. It united promptly, and two years afterward it would have been hard to tell which thumb had been injured."

I wish to add another case which I think is equally remarkable. Twenty-four years ago while playing with my cousin—a girl eight years of age—I had the misfortune to cut off the end of her finger. We were playing with a hay-cutter, I was turning the crank and she was pushing in the hay. She pushed her hand a little too far, and the result was she lost a portion of her second finger. It was taken off smoothly just back of the nail. We both ran to the house, where the wounded finger was hurriedly dressed, and I was despatched for the doctor, who lived over a mile away. He happened to be at home, and we returned as soon as possible, but it was more than an hour from the time the accident occurred before he arrived at the house. At the earnest solicitation of my mother, and as he said against his better judgment, he finally consented to attempt to secure the severed piece to the stump. He disclaimed all responsibility in the case, however, and said it was worse than useless, as it would surely mortify, as it had been severed so long, and was stone-cold and blue. He also feared blood-poisoning.

Suffice it to say that it united promptly—that is, the bone did, the flesh on the under side of the finger sloughed off, but afterward filled in nicely by granulation. The nail also sloughed away, and a new nail formed, and two years afterward no one could tell from the dorsal surface which finger had been injured. On the palmar surface there was a well-marked cicatrix running around the end of the finger, and it seemed to taper a little more than the corresponding finger on the other hand. As this was her right hand, it was extremely fortunate that the attempt was made to save the severed piece. She never experienced the slightest difficulty in playing the piano, which made a pretty good test as to the usefulness of the finger.

C. L. Dodge.

Kingston, N. Y., Feb 25, 1888.

NEWS ITEMS.

The Case of His Imperial Highness, the Crown Prince of Germany.—Sir Morell Mackenzie forwards to the London weeklies of February 18, 1888, the following statement:

His Imperial Highness, the Crown Prince of Germany, having expressed his wish that I should now place on record my opinion of his case, the opportunity is afforded of correcting some of the statements which, from time to time, have been inaccurately attributed to me.

The general idea is that I am of opinion that the disease from which His Imperial Highness is suffering is not cancer;[1] the view on the other hand, which I have consistently maintained is, that there never has been any proof of the existence of cancer.

To enter more in detail: When I arrived in Berlin, last May, I stated to my colleagues that, in my opinion, the appearances seen in the throat were of a negative character—that is to say, that the disease might be either benign or malignant, and that its nature could only be determined by microscopical examination. A portion of the diseased tissue having been taken away by me from the throat of His Imperial Highness, it was submitted to Professor Virchow, who could not detect in it anything of a malignant nature. Repeated examinations by Professor Virchow of other portions removed by me yielded similar results.

In the month of July, whilst His Imperial Highness was staying in the Isle of Wight, I pointed out to more than one of his august relatives that the danger that I most dreaded was the occurrence of perichondritis at a future date, and three months later this fear was proved to be well grounded. At the end of October and early part of November, entirely fresh symptoms appeared, and at that time the local disease presented an appearance which was consistent with the diagnosis of cancer. It was then impossible to obtain any fresh microscopical evidence in the matter, and I considered it safer accordingly to treat the case as one of a malignant nature; at the same time, however, I drew up and submitted to my colleagues a *protocol*, in which I stated that although the disease at that moment looked like cancer, I could not agree that the malady was proved to be malignant until a further microscopical examination had been made. The document in which I set forth my views was forwarded to Berlin to be placed in the State Archives. Although the unfavorable symptoms then present were explicable on the ground of the existence of cancer, yet it was clear to the majority of the physicians at that time in attendance that perichondritis had supervened.

In the middle of December, however, the unfavorable signs had passed away, and there were no longer any clinical symptoms of cancer. Microscopical evidence on the subject was, however, still wanting. This was furnished at the end of January, when a slough was expectorated from the very spot which had presented such a highly suspicious appearance in November. This slough was most carefully and repeatedly examined by Professor Virchow, and the result (which is now published) again shows that cancer could not be detected.

To recapitulate: In my opinion the clinical symptoms have always been entirely compatible with non-malignant disease, and the microscopical signs have been in harmony with this view. I need only add that although in nearly every case of laryngeal disease it is possible at

[1] In this statement the words "cancer," "cancerous," and "malignant," are used synonymously.

the first inspection to form an accurate opinion as to the nature of the disease presenting itself, yet, in a few rare instances, the progress of the complaint alone permits its character to be determined. Unfortunately, the case of His Imperial Highness is among the latter number, and at this moment medical science does not permit me to affirm that any other disease is present than chronic interstitial inflammation of the larynx combined with perichondritis.

The Lancet, in commenting on the above, says that it amounts to this, that Sir Morell Mackenzie sees no absolute proof that the disease is malignant or cancerous in nature. What all Europe is anxious to know is, whether Sir Morell Mackenzie and the eminent German doctors associated with him can find proof that the disease is certainly not cancer, and this knowledge appears, for the present at least, to be unattainable. One of the most painful circumstances in the case has been the uncertainty as to the diagnosis ever since May last. And now, after nine months, the same uncertainty continues. We would gladly, if we could, read Sir Morell Mackenzie's statement in another sense; but it is very precise and clear, and it is impossible to find in it anything that implies that in his opinion the disease is certainly not cancer. The only consolation to be derived from this latest report is the very small one that the opinion is, at any rate, less unfavorable than if it had been a confirmation of the diagnosis of cancer. Professor Virchow's report is purely negative, and the material submitted to him was evidently incapable of throwing any light upon the nature of the disease.

A Babies' Hospital a Nuisance.—Suit has been brought in New York City to put an end to the maintenance of a babies' hospital in a residential quarter, on the ground that it is a nuisance and dangerous to the health of the neighborhood.

Precautions to be taken when Attending Smallpox Patients.—The Iowa State Board of Health publishes the following directions, in its bulletin for February, 1888:

Several physicians have asked us what are the best means of protecting themselves—their person and clothing, when they are called upon to attend cases of smallpox, so that without risk of carrying the disease, and infecting others, they may continue their general practice.

The following plan we believe to be perfectly safe: There should be worn a loose gown of glazed muslin, long enough to cover the feet, buttoning closely at the neck and wrists, and having a waistband; the head—all the hair, if possible—covered by a cap of like material. This should be put on out-of-doors and taken off on returning from the house. After removing the cap and gown, the hands, face, and all the exposed parts of the body should be washed well in soap and water and then rubbed freely with a weak solution of corrosive sublimate, the best germicide known. Physicians should not be expected to make unnecessary visits, as usually with good nursing and care, but little medicine will be required. Wearing apparel, such as coat, vest, and pants, that cannot well be washed or boiled, can be thoroughly disinfected by steam, hot air (212° F.), or by sprinkling them and pressing them slowly and thoroughly with a flat-iron as hot as can be used without burning the goods. But little confidence can be put in sulphur fumigations.

The Age of University Professors.—A movement is on foot in Paris to enact a limit of age for University professors. Sixty-five is suggested as a suitable age for superannuation for all future professors, and seventy for those at present in office.—*Medical Press.*

The Domestic Use of Saccharine.—A correspondent writing in the *Scientific American* of February 18, 1888, relates his experience in using saccharine as follows:

Sugar being a prohibited article to me, I naturally became interested in Fahlberg's "saccharine," and obtaining a supply as soon as possible, began experimenting with it. Using it alone to sweeten lemon juice or stewed cranberries, I found it very difficult to mix, and tried various dodges to remedy it, all of which had some drawback or other until I thought of dissolving it in glycerine.

I found that for general purposes the formula of glycerine one pound, saccharine one drachm, heated to solution, was the best. Two teaspoonfuls of above to the juice of one lemon made up to eight fluidounces make a lemonade sweet enough for almost any one, and three teaspoonfuls to four ounces of stewed cranberries make a dish "fit for a king."

I gave a sample of the above to a gentleman to whom sugar was tabooed, and who was then using saccharine alone, and asked him to try it with cranberries and report. When next seen he said very enthusiastically, "That's splendid. I've bought a barrel of cranberries, and would not go back to sugar if I could."

The advantages of the mixture over pure saccharine are: That the glycerine gives it a body, and the mixture very closely resembles in taste and appearance the best white honey; that it dissolves readily in water, milk, tea, and coffee, wines and liquors; and that it can be very readily measured.

The Ownership of Prescriptions.—The *American Druggist* discusses this question as follows:

So far as we know, the ownership of a physician's prescription has been brought before the courts, heretofore, only in a one-sided way, and has not been argued from the standpoint of special agreement or contract. It is usually supposed that when a patient calls upon a physician for advice, the advice constitutes the commodity which the physician has to sell for the time being, and that, if he writes a prescription and delivers it to the patient, receiving his fee, the commercial transaction is completed. In other words, it is supposed that the advice, including the prescription, are tantamount to a bona fide sale on the part of the physician, and to a bona fide purchase on the part of the patient, so that the latter may be regarded as the owner in fee simple of the prescription. But a sale or purchase may be regarded, or, rather, should be regarded, as a form of contract, entailing certain obligations upon both parties. When there are no conditions surrounding the exchange of the commodities, except the act of handing over the consideration, the transaction is absolutely completed and the contract fulfilled, as soon as the consideration is paid. But if the sale is made under certain conditions, accepted by the purchaser, the case assumes an entirely different aspect. We hold that if a physician expressly writes upon a prescription: "This prescription is intended for a special case and occasion and is not to be repeated"—or words

to this effect—and if the client accepts the prescription with this condition, then the latter is bound to abide by he condition. We believe, if a case of this kind were properly argued before the courts, it would be decided as we have outlined. But such a decision would hardly be of much practical value, because all that would be needed to evade the condition would be for the client to copy the prescription with omission of the prescriber's name and all details which might show that it was intended for a special case and occasion. Since any one may combine medicines in any manner, or shape, and several prescribers often happen to combine the same ingredients in the same proportions, it would be impossible for the original prescriber to identify—in a legal sense—his own prescription which he had given or sold to his patient conditionally.

Practically, therefore, even the acknowledged or assumed right of the physician to limit the use of any of his prescriptions to a particular case or time, could be easily circumvented, unless laws should be enacted which would clearly define the rights of prescriber and client.

Shakespeare's Medical Friend.—The *Medical Standard* for February, 1888, in reply to a question as to who this privileged person was, states that as the matter is of some general interest the epitaph on the tombstone in the Virginian church-yard may be cited: "Here lies the body of Edward Heldon, Practitioner in Physick and Chirurgery. Born in Bedfordshire, England, in the year of our Lord 1542. He was a friend and one of the pall-bearers of William Shakespere, of the Avon. After a brief illness his spirit ascended in the year of our Lord 1618, aged 76." It is sufficiently evident from this epitaph, and his daughter's marriage to Dr. Hall, that Shakespeare mingled in medical society.

A Simple Diagnostic Test for Ovarian and Ascitic Fluid.—Prof. Mayet advocates the use of sulphate of magnesium in order to distinguish between ascitic liquid and that from an ovarian cyst. If it be added in excess to the former, a precipitate is formed of paraglobulin and fibrinogen. In the latter no precipitate occurs.—*Medical Press.*

"Tempus Edax Rerum" for Hypochondriasis.—A case not less instructive than amusing is, the London correspondent of the *Irish Times* says, about to come to legal issue in London before long. Two years ago a London doctor had on his list of patients a lady long suffering from an affection of the face and jaw, which baffled the arts of the faculty. She changed her residence from London to a provincial town, but kept herself in the hands of her London doctor by letter. Finding the ailment obstinate, and the patient somewhat hypochondriacal, the doctor wrote in the end, saying he had exhausted his resources, and adding his opinion that *Tempus edax rerum* was the only remedy. Straightway the lady hied herself off to a local chemist, and applied for the specific as set forth in the letter. The attendant, it will be contended, through deliberate dishonesty, made up a bottle for which he charged 7s. 6d., and at the patient's request registered her name as a customer to whom the remedy was to be regularly supplied. She continued using and paying for the sham medicine for over a year and a half. Coming to London for the Jubilee, she chanced to meet her former doctor who was astonished to find himself gratefully thanked for his invaluable prescription. He wrote at once for an explanation, and the next stage of the business began with the disappearance of the assistant, and the denial of any responsibility of the chemist, but, nevertheless, the case stands for trial. The plaintiff has, it seems, been an invalid from her twentieth year, and has paid for medicine alone over £2000.

A Beautiful Clinical Case of Glanders.—The *Medical Press* reports that a curious case put the diagnostic ability of a well-known French therapeutist to the test on a recent occasion. The patient was a working saddler, who presented a number of small, superficial abscesses in different parts of his body, the secretions from which, under the microscope, showed the presence of the characteristic bacillus of glanders. After due consideration, the patient was pronounced to be suffering from farcy, and was exhibited at the Hospitals Medical Society of Paris, as such. Certain members having expressed a doubt as to the accuracy of the diagnosis, some experimental inoculations were made with matter taken from one of the sores, but without any result. Ultimately it was discovered that the man was a confirmed morphiomaniac, taking from six to eight hypodermatic injections daily. The abscesses were caused by a want of cleanliness, and by too superficial injections. What a magnificent case for the clinical examination of students!

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM FEBRUARY 14 TO FEBRUARY 27, 1888.

ARTHUR, WILLIAM H., *Captain and Assistant Surgeon.*—Leave of absence extended two months.—*S. O. 35 A. G. O.*, February 13, 1888.

VOLLUM, EDWARD P., *Lieutenant Colonel and Surgeon.*—Granted leave of absence for four months, with permission to go beyond sea and to apply for an extension of two months.—*S. O. 41, A. G. O.* February 20, 1888.

GARDNER, E. F. *Captain and Assistant Surgeon.*—Granted leave of absence for one month and twenty-one days.—*S. O. 41 A. G. O.*, February 20, 1888

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING FEBRUARY 25, 1888.

WILLIAMS L. L., *Passed Assistant Surgeon.*—Promoted and appointed Passed Assistant Surgeon from Feb 10 1888. Feb. 23, 1888

COBB, J. O., *Assistant Surgeon.*—Appointed an Assistant Surgeon, Feb. 21 1888 Assigned to duty at Marine Hospital, Chicago, Illinois, Feb. 25, 1888.

STONER J. B., *Assistant Surgeon.*—Appointed an Assistant Surgeon Feb 21, 1888. Assigned to duty at Marine Hospital New York City, Feb. 23, 1888

CONDICT, A. W., *Assistant Surgeon.*—Appointed an Assistant Surgeon Feb. 21 1888 Assigned to duty at Marine Hospital, Chicago, Illinois, Feb 23, 1888.

ORIGINAL ARTICLES.

A CASE OF SÄNGER'S CÆSAREAN SECTION.

BY L. E. NEALE, M.D.,

DEMONSTRATOR OF OBSTETRICS IN THE UNIVERSITY OF MARYLAND, JUNIOR OBSTETRICIAN TO THE FREE LYING-IN HOSPITAL.

H. J. C., colored; low stature; aged twenty years; Maryland; not married; no miscarriages; primipara; entered the Free Lying-in Hospital of the University of Maryland during the last month of her first and only pregnancy complicated by hydramnios.

Labor began December 11, 1887, at 4 A. M.; membranes ruptured at 8 A. M. before full dilatation of the os; Bandl's (retraction) ring appeared at 10 A. M. and steadily developed; Tarnier's forceps (Prof. Wm. T. Howard's modification) applied with difficulty at 1 P. M. to head movable above superior strait in R. O. I. P.

The operation lasted for one hour and three minutes without result, save bruising the child's scalp, and left both mother and child in apparently good condition.

The entire escape of liquor amnii, firm uterine contraction and retraction over the child, and the well-marked Bandl's ring dividing the uterus into two upper and lower segments would have rendered an attempt to perform version by any method exceedingly dangerous, and its execution, I believe, practically impossible. The cause of dystocia was a generally contracted, non-rachitic pelvis.

A consultation between Profs. Miltenberger, Tiffany, Michael, and myself, resulted in favor of Cæsarean section, and against craniotomy on the living child. The woman was willing to abide by our decision, and, accordingly the Sänger operation was performed at 6.15 P. M., Dec. 11, 1887. The operation lasted one hour and a half under gaslight; chloroform was the anæsthetic, and bichloride of mercury the antiseptic used.

Abdominal and uterine incision both in anterior median line. Placenta not in line of incision, but attached to the left, posteriorly. Child was readily extracted by feet, and with difficulty resuscitated. The uterus did not escape from the abdominal cavity until after removal of child, when it was small by contraction and retraction of its muscular walls.

After the first slight gush consequent upon opening the sinuses there was but little oozing from the uterine incision, which was entirely checked by placing an elastic ligature around the supravaginal cervix, which was not constricted prior to removal of the child.

The placenta was spontaneously expelled through the wound and the membranes gently removed by hand; the loss of blood during the entire operation being slight, indeed, not more than usually occurs in an ordinary case of natural labor.

Peritoneum dissected up and uterine wall resected along uterine incision; twenty-one deep silk sutures including serous and muscular coats, and twenty-nine superficial catgut seroso-serous Lembert sutures were used to close the uterine wound.

The uterine appendages were ligated and removed. Abdominal cavity washed out with warm water, elastic ligature removed from cervix, and the closure of the abdominal wound with a single layer of twenty-two deep silk sutures completed the operation. The intestines did not escape from the abdominal cavity, but during part of the time occupied in closing the uterine wound and removing the appendages the uterus did, and whenever thus exposed was constantly covered with warm, moist, antiseptic cloths.

The woman never rallied from the operation, and despite all stimulation died in forty-four hours of shock.

Post-mortem two hours after death revealed: intestines distended; slight deposits of fresh lymph here and there on intestines; a small cord-like band of omentum slightly adherent to right horn of uterus. Abdominal cavity dry, peritoneum for the most part normal, congested in places with slight lymph deposits. Uterine wound dark and sloughy. Not the slightest union of either uterine or abdominal incision. Heart and other organs perfectly normal.

Diagnosis.—Slight traumatic peritonitis; death from shock.

Diameters of pelvic brim[1]	antero-posterior	2¾ inches.
	transverse	4¾ "
	oblique	4¼ "
Diameters of fœtal head[2]	occipito-frontal	5½ "
	suboccipito-bregmatic	4¾ "
	occipito-mental	6 "
	fronto-mental	4 "
	biparietal	4¼ "
	bitemporal	3½ "
	bimastoid	3¾ "
Circumference[2]	occipito-frontal	14⅜ "
	suboccipito-bregmatic	13¼ "

Length . . 19½ inches. Weight . . 8 lbs. 14 oz.

The head was hard, thoroughly ossified, non-compressible, and as the above measurements and clinical

[1] These measurements were verified after death, when the abdomen was opened and the pelvic organs removed.

[2] These measurements were taken after birth, as I know of no means of measuring the fœtal head before delivery

history actually demonstrate, could not have been delivered, *per vias naturales*, by any conservative or non-destructive operation. The child's head and face were much contused by the forceps, a part of the left cheek subsequently sloughing out, and consequent pyæmia resulting, but he is now a fine thriving boy.

"Inasmuch as neither hemorrhage nor passage of lochia into the abdominal cavity occurred, the technique of the operation could not be blamed for the result."[1]

Owing to my limited experience with this operation, and the amount of recent literature upon the subject, it would be pedantic in me to say more about the technique.

I need only mention the fact that the best authorities are now adopting the anterior median incision for both abdomen and uterus, and that silk and catgut, I believe, are superseding silver wire as suture material. In my case it was impossible to fold in the peritoneum over the uterine incision without resecting the muscularis, and accordingly this was done. The sutures were probably as many as four to the inch, and although the authorities recommend close suturing, I am now of the opinion that the sutures in this case were unnecessarily numerous.

Yet, were I asked, what one avoidable cause contributed more to the woman's death than another, or rather, what part of the treatment I considered most open to criticism, I should frankly answer: in my opinion it was the unnecessarily prolonged and severe high forceps operation. My only excuse for this was my desire to avoid, if possible, the more serious operations of craniotomy on the living child, or Cæsarean section. And just here, I honestly believe, lies the common error in the treatment of this class of cases, viz., too much preliminary or conservative tampering.

THE MEDICAL NEWS of December 10, 1887, says editorially: "The fact is established, that, to be successful, Cæsarean section should take precedence of the forceps, turning, and craniotomy, trials of which only waste valuable time, and add to the risk of the knife." But in these cases of minor degrees of pelvic contraction, I believe it is often practically impossible to foretell, without an actual fair trial, whether the less dangerous conservative operations offer no chance of delivery through the natural passages. Such being the case, we would naturally resort to pelvic mensuration for a satisfactory solution of the difficulty. But unfortunately, in the present state of our knowledge on this subject, pelvimetry on the living subject especially when *in partu*, is not always sufficiently practicable, accurate, or reliable, to enable us to determine, by that alone, in cases of minor or slight contraction, between such momentous questions as the various comparatively mild conservative measures on the one hand, and craniotomy of the living child, or Cæsarean section on the other.

Cæteris paribus, I consider him a bold man, indeed, who would unhesitatingly cast the beam for life or death of the unborn human being merely by the addition or subtraction of a fourth or a third of an inch in pelvimetry. This is patent when we remember that there is only one diameter of the pelvic brim, the conjugata vera, that can be measured sometimes, not always, under certain favorable conditions, not under all, with any degree of positive or absolute accuracy.[1] But it is still more palpably true when we remember that we have no means of accurately measuring the head, or, indeed, any other part, of the unborn child, and this fact alone must necessarily invalidate, and that to a considerable extent, the practical importance of pelvimetry in the class of cases under consideration.

Neither is the resistance of the maternal soft parts, nor the compressibility of the fœtal skull, identically the same in all cases. And would it be far amiss to say that the ability of the operator, the condition of the patient, and her surroundings may often more or less determine the nature, and particularly the result of the operation?

It is true that Michaelis and Barnes have each delivered through a pelvis of one and one-half inches antero-posterior diameter, and Dr. Osborn, in the celebrated case of Elizabeth Sherwood, through a three-quarter inch pelvis with success to the mother, but by a *destructive operation* on the child, and is it not possible that a Sänger or other conservative operation might have extended success also to the child?

"Dr. Parry collected seventy cases of craniotomy in pelves measuring two and a half inches, and under. Of the seventy women, forty-three survived, and twenty-seven died, a maternal mortality of nearly forty per cent. The work was not done by tyros, but by celebrated obstetric surgeons."[2] If this occurred in pelves of two and a half inches, and under, with head presumably of normal size and resistance, is it not fair to suppose it might also have occurred in pelves of two and a half inches and a little over, say two and three-quarters (my case), with a head considerably above normal, both in point of size and resistance, as in the instance herein reported?

With reference to my own case, I consider it is a fair supposition when we bear in mind the important

[1] Abstract by E. H. G. from Sänger's Article, Amer. Journ. of Obst., vol. xix. p. 222.

[1] I state this under the practical conviction that in minor degrees of pelvic contraction, external pelvic mensuration is exceedingly inaccurate, and wholly unreliable, whilst internal pelvic mensuration is possible only under certain favorable conditions, and is even then rarely absolutely accurate.

[2] Lusk, ed. 1885, p. 490.

fact, that here the pelvis was contracted not alone in the antero-posterior diameter, but in all other diameters, and hence belonged to that more difficult and dangerous class of generally contracted pelves.

Lusk tells us that of five women with generally contracted pelves, in which the conjugate ranged from three to three and a quarter inches, and operated on by Naegèle, Heim, Spiegelberg, Lusk, and Kormann, all died as a consequence of delivery through the natural passages.[1] My case had a two and three-quarters inch conjugate.

Now let us turn from such results as these to the more pleasing picture of the modern or improved Cæsarean section.

The Medical News of December 10, 1887, states that "the first fifty Sänger-Cæsarean operations of continental Europe, which were completed in March, 1887, resulted in the saving of forty women out of fifty and forty-eight of their children!" With commendable boldness (for we need positive guides and rules to direct us in these matters) The News asserts the belief: "That the Sänger operation promptly conducted is less dangerous to the woman than craniotomy, where the true conjugate of the pelvis is reduced to two and a half inches!"

But, I ask again, Can we always measure a pelvis so accurately as to decide this vital question? Should we extend this limit if the pelvis be *generally* contracted or the head *above normal* either in point of size or ossification. Is such a rule affected by the life or death of the child, the surrounding conditions, the skill of the operator, etc.? These questions I leave for others to answer.

That in general, with minor degrees of pelvic contraction, the Sänger-Cæsarean section is a far more dangerous operation for the mother than craniotomy on the living child, I frankly admit; but I would ask, Is it fair or justifiable merely for this reason to disregard utterly the life of a viable and actually living human offspring by the performance of the latter operation when statistics prove there is a great possibility of saving both child and mother by the former procedure?

This I leave as an open question; but be it remembered, at the last International Medical Congress, 1887, it was the prevailing opinion among those who participated in the discussion on Cæsarean section, that the Sänger operation should hold precedence over craniotomy on the living child! Lusk emphatically declared that, "the Cæsarean section was easy to do and he did not want to encourage trying craniotomy and then Cæsarean section, but should make the latter the operation of election."[2]

In The Medical News of September 18, 1886, Dr. R. P. Harris published a table of all the Sänger operations that had been performed up to that time, with the result of saving 68 $\frac{8}{19}$ per cent. of women in all countries and 78 per cent. in Europe alone. The News of December 10, 1887, stated that "prior to 1887, the Sänger cases of the United States were all fatal, because operated upon *in extremis*: but during this year there have been, in all, three of this class of operations, two of them in hospital, saving all of the women and two of their children.[1] We hope to see the Cæsarean operation in the United States differently conducted in the future, and women subjected to the knife in good season, so as to save both child and mother." In a note from Dr. Harris, of Philadelphia, dated December 14, 1887, he states: "There have been 8 Cæsarean operations, 6 of them Sänger's, in the United States during the last nine months. All children alive, 2 soon died, 4 patients recovered. There have never been as many Cæsarean cases in the United States in one year before."

With regard to the case herein reported, I can frankly say, that it is only the result I regret, as I consider the operation to have been perfectly justifiable and plainly indicated, and in this opinion all the consultants fully agree.

THE GALVANO-CAUTERY IN THE TREATMENT OF ENLARGED TONSILS.[2]

By FRANK HAMILTON POTTER, M.D.,
Lecturer on Laryngology, Medical Department, Niagara University, Buffalo, N. Y.

In a note to the last International Medical Congress, M. De Saint-Germain says: "He who invents a surgical operation receives great credit. Recognition, at least, should be given him who substitutes for two operations two simple procedures, less dangerous, quite as effective, and more easy to perform."[3] One of the procedures thus suggested was ignipuncture of the tonsils in the place of tonsillotomy. And while the advantage of this procedure is very evident, its claim to priority cannot be maintained. Some time before, Voltolini had advised cautery puncture of the tonsils, and Dr. S. Solis-Cohen had called attention to the same thing. Moreover, the paper of Dr. Charles H. Knight on the "Galvano-cautery in the Treatment of Hypertrophied Tonsils," read before the American Laryngological Association at its last meeting,[4] and the discussion thereon showed that the minds of many surgeons had been turned in this direction. The

[1] There have been several other successful cases in the United States, one in our own city subsequent to this writing, as yet, I believe, unpublished.

[2] Read before the Medical Society of the State of New York, Feb. 7, 1888.

[3] The N. Y. Medical Record, Sept. 10, 1887

[4] The N. Y. Medical Journal, Sept. 24, 1887.

writer himself had been working upon this subject, and the opinions of the various observers above referred to, served on the whole to confirm his views and encouraged him to persevere in his investigations. The purpose of this paper is to call attention again to the use of the galvano-cautery in the treatment of enlarged tonsils, and to present, in a general way, some suggestions founded on a year's experience with it.

The subject divides itself into two parts:

1. The method of procedure; and 2. A consideration of some of the objections that have been raised to the use of the galvano-cautery for the relief of this condition of the tonsils.

We can apply this method of treatment in two ways, either with the galvano-caustic snare, or with the sharp-pointed electrode. The latter is, in the writer's opinion, to be preferred, though for the sake of completeness a description of the former is given. In using the caustic snare the platinum wire must be adjusted closely to the tonsil, care being taken not to include as much of the organ as it is proper to remove. This is because the heated wire will cauterize that part of the organ that remains, causing it to contract to a considerable degree. Red heat is the best, and the wire must be tightened only during the passage of the current, which must be allowed to flow intermittently. In this way the wire plows slowly through the tonsil, little by little, removing a sufficiently large part of it, and leaving the stump well cauterized. The time required depends upon the size of the tonsil and the dexterity of the operator, but the current must be interrupted several times, as the best results are obtained when the operation is performed with deliberation. There is very little after-treatment, the wound healing readily under alkaline washes. It is important not to allow the wire when heated to come in contact with the pillars of the fauces or other parts, as these have more sensation than the tonsils, and if burned cause a good deal of pain. No. 30 platinum wire has been found to be the best, as, to borrow the words of Dr. Knight, it is readily heated, easily manipulated, and cuts the tissues with great facility. The advantage of the caustic snare over cautery puncture is due to the fact that it is more rapid, but, on the other hand, it is more painful and less easily managed, and we have, for these reasons, come to prefer the latter. Its application is simple. A sharp-pointed electrode, under red heat, is plunged deeply into the tonsil, say to the depth of three-eighths of an inch, held there for a moment and then withdrawn. Generally a second puncture can be made at the same sitting. Four to seven days must then be allowed to elapse, and the operation repeated. The average number of sittings required is five, but in exceptional cases with large tonsils this may be increased to eight or ten. This treatment causes but little pain, and none at all under preliminary applications of cocaine in the strength of four to eight per cent. The after-treatment consists simply in the use of alkaline gargles. The tonsil is finally contracted to its normal size and the symptoms dependent upon its enlargement entirely relieved.

It has been urged against this treatment that it cannot be used in all cases; that many people have an aversion to being burned; that it is impracticable in young children without general anæsthesia; and that, at the best, it is slow and tedious.

Now, we do not know any treatment of any disease that can be used in all cases; and we have found many people who have had a strong aversion to the use of any cutting instrument upon them. There may be, and are some conditions which will preclude the use of the galvano-cautery in the treatment of enlarged tonsils. One of these conditions may be an aversion to being burned. Certainly in this case we should not only not urge but advise against its employment. The noise of the burning tissues and the unpleasant odor produced are so disagreeable to some patients that they will not submit to this treatment. There is no other course open to us under these circumstances but to employ some other method. In regard to the necessity of using general anæsthesia with young children, we find this is often required in any procedure connected with the removal of their tonsils, and when this is necessary the operation should be completed at one sitting and that method employed which will accomplish this most readily. In most instances, however, we believe that kindness and patience will lead even young children to submit to cautery puncture, especially if they can be made to appreciate that you will cause them no pain in the application you desire to make.

The objection that this method is slow and tedious as compared with amygdalotomy is true, but before we decide in favor of the latter we ought to consider that the increase in the rapidity of the operation is attended with an increase of the danger. At any rate, it is pertinent to remark that an operation done well is done soon enough, and that that method should always be selected which increases the safety of the patient.

The danger of any cutting operation upon the tonsils, whether with the bistoury or with the amygdalotome, has to do with the hemorrhage. Opinions differ very much as to the degree of danger from hemorrhage after these operations. It may be said, however, though serious danger is not frequent, yet the liability to a fatal result from this cause is always present. Reports of cases of alarming and obstinate hemorrhage after tonsillotomy are not so rare as to encourage the belief that the operation is a simple one, and free from danger. Within our

own State, during the last year, such skilful operators as Dr. H. B. Sands[1] and Dr. Clinton Wagner[2] have reported such cases. So serious were these that it is conceivable that a slight variation in the circumstances attending them might have led to a fatal termination. Indeed, a fatal result is not so very uncommon. At the International Laryngological Congresses a number of deaths from this cause have been reported, and such men as Schnitzler, of Vienna, Schmidt, of Frankfort, and Michel, of Cologne, are on record as saying that they never under any circumstances cut an enlarged tonsil. And Dr. Harrison Allen[3] may be quoted as saying that he has given up for a long time the use of the bistoury and tonsillotome, on account of the bleeding attending them. He belongs to the class of timid operators in these cases, and thinks it would be very little consolation to a patient whose carotid required ligation to be told that this was a very rare accident. Elsberg, at the American Laryngological Association, in 1881, reported eleven thousand cases of tonsillotomy without a fatal result; but in two cases it was necessary to tie the carotid; in several the hemorrhage was so serious as to blanch not only the patient but also the cheeks of the operator, and in ten cases it was so vigorous as to require the most energetic treatment before it could be controlled.

Now, it seems to us that one fatal case would more than balance any number of successful cases, and while we do not wish to appear as an alarmist, we hold that any method tending to remove even the rare danger of fatal hemorrhage should be adopted. Such a method, we believe, has been found in the use of the galvano-cautery, as already indicated.

Some discussion has taken place as to whether cautery puncture is efficient in the case of a hyperplastic tonsil, it being admitted that in the condition of a simple hypertrophy this method has produced good results. The title, "enlarged tonsils," was purposely selected to indicate the writer's opinion on this subject. Wherever lately he has found the tonsils increased in size to a degree warranting an operation, he has employed the method of cautery puncture, and with uniformly good results. Of course, as the organs are not removed by this operation, it is impossible to tell just their pathological condition, but there is good reason to believe that whenever the tonsils are enlarged the application of the galvano-cautery as described will be sufficient for their reduction.

One more suggestion: the function of the tonsils is not yet determined. Whether they have a blood-forming function, or merely absorb from the saliva certain ingredients that would otherwise be wasted, or whether they are invested with both these functions, it is certainly conservative and wise not to destroy them entirely, but rather to preserve them so that, if even to a slight degree, their purpose in the economy may be performed.

The advantages of treating enlarged tonsils by the galvano-cautery, especially by the method known as cautery-puncture, may be formulated as follows:

1. It is safe.
2. It is easily managed.
3. It is painless.
4. Though slow it is sure, and preserves rather than destroys organs which it is rash to say are of no use whatever in the economy.

APEX EXPANSION VERSUS PURE AIR IN PULMONARY CONSUMPTION.[1]

By THOMAS J. MAYS, M.D.,
PROFESSOR OF DISEASES OF THE CHEST AT THE PHILADELPHIA POLYCLINIC.

Next to the tubercle bacillus, impure air stands most prominent among the many agencies which have been assigned as the causes of pulmonary consumption. Innumerable plans and methods have been devised and proposed for improving the ventilation of our dwellings, hospitals, and workshops; volumes upon volumes have been written on the ill effects of breathing vitiated air; and the immaculate freshness of the country and mountain air has come to be universally regarded as a certain guarantee against pulmonary consumption. These, like many other popular notions, contain a germ of truth, but actually are delusive, inasmuch as they exaggerate the effects of a small evil, and afford a false sense of security against the real source of danger in the production of this disease. This we shall endeavor to show in the following pages.

At the very outset we desire to be well understood that we do not in the least underrate the value of fresh, wholesome air in the prevention and treatment of pulmonary consumption, and while it is probably true that on the whole country people enjoy greater immunity from this disease than city people—though this is not proven on account of a lack of adequate statistics—yet we are convinced that the purity of the atmosphere plays a very small part in bringing about this probable result. If we are permitted to make a homely, hypothetical proposition, we will state that if two individuals who require the same quantity of air, and who are equally well off so far as heredity, food, clothing, warmth, comfort, etc., are concerned, were both enjoined to maintain a sedentary and a stooped position of their bodies for an unlimited period, one inside of a house and the other outside in the open air, we have no reason for

[1] Read before the Philadelphia County Medical Society, February 22, 1888.

believing that the one inside will fall a victim to this disease sooner than the one on the outside.

If it were true that this disease is the result of breathing a vitiated and impure atmosphere, how can we account for the fact that the inhabitants of Iceland, Greenland, Lapland, and of other cold countries of the north, who live in dwellings which are notoriously wanting in ventilation, are practically exempt from this disease? Of the Icelanders, Mr. Warnford Lock,[1] who is very familiar with these people and who speaks their language, says that their life is

"one long exposure to the elements, and during the night they live in dwellings devoid of ventilation, and which, if not buried beneath the earth, are built of turf and often become grass-grown, a very bad feature being the excessive stuffiness of the common living and sleeping room, where, owing to the absence of fires, the greatest possible crowding and plugging are necessary in order to maintain a tolerable degree of warmth."

And yet Dr. Cullimore,[2] from whose work the above quotation is taken, says (p. 73)

"that consumption in Iceland is never indigenous, but is always, when it does occur, imported from abroad and but seldom extends to the second native generation."

On the other hand, it may be stated that the people of the tropical regions of the globe who enjoy an uninterrupted revelling in pure, fresh air, both day and night, winter and summer, are by no means free from pulmonary consumption. The only difference, so far as the physical life of these two classes of people is concerned, is that the warm climate, which produces such a luxurious atmosphere, also creates a tendency to physiological sluggishness and an indisposition toward physical exertion among its inhabitants; while the people of the cold and rigorous north are compelled to maintain the warmth and vitality of their bodies in great part, by day, through physical exercise, of which their occupations of hunting, fishing, herding, etc., give them a full share. It is also well known that miners and laborers employed in coal mines, who continually respire an atmosphere which is not only loaded with impurities, but is damp and musty, suffér but very little from this disease.

One fact which lends color to the belief that pure air is such an essential element in limiting the ravages of consumption, is that those who occupy elevated or mountainous regions are less liable to this disease than those who live near the sea level. Thus Fuchs shows from extensive data that "at Marseilles, on the seaboard, the mortality from this disease is 25 per cent.; at Oldenburgh, eighty feet above the level of the sea, it is 30 per cent.; at Hamburg, forty-eight feet above the sea, it is 23 per cent.; while at Eschevege, four hundred and ninety-six feet above the sea level, it is only 12 per cent.; and at Brotterode, eighteen hundred feet above the sea, it is but 0.9 per cent."

Carrying this line of observation further, it appears very probable that consumption is almost unknown among any native people who live more than 6000 feet above the level of the sea.

Now that which concerns us here chiefly is the reason why mountain climates are, as a rule, so free from pulmonary consumption. Is it because the atmosphere is pure and free from septic germs? This is hardly possible, for if it were true that the aseptic condition of the air plays any prominent part, why should the Icelanders, who nightly reek in a most filthy atmosphere; or the dwellers along the Nile, who, according to Mr. B. Phillips, live "in huts where the pure air has neither ingress nor egress, except through a small hole near the ground;" or the coal miners, who continuously respire a foul and poisonous atmosphere, all be comparatively free from this disease? Is it due to the general absence of humidity? We think not, for Bogota, the capital of the United States of Colombia, located on the Andes, near the equator, at an elevation of over 9000 feet, is said to be entirely exempt from this disease, although dampness prevails to quite a large extent. We think there is much reason for believing that it is principally, if not entirely, on account of the attenuated condition of the atmosphere, and shall, therefore, at once proceed to consider the physiological influence of high altitudes on the human body.

It is estimated by Dr. Denison that at an elevation of 6000 feet the surface of the body is relieved of nearly 7000 pounds pressure. When such an enormous weight is lifted from the body it is quite evident that its interior must also be markedly affected—the pulse is accelerated from fifteen to twenty beats per minute; the respiration is quickened from ten to fifteen breaths per minute; evaporation from the skin and lungs is increased, and the amount of urine is diminished. These are some of the immediate effects. Protracted residence in such a high region enlarges the chest capacity. The Quichua Indians, who dwell on the elevated table lands of Peru, have enormous-sized chests, containing capacious lungs with large air cells. The Mexican Indians possess chests which are out of proportion to the sizes of the individuals. Dr. Denison says that children born in the Rocky Mountains have chests of unusually large capacity, and M. Jaccoud states that at St. Moritz the respirations are not only more frequent, but fuller.

The reason why the number of respirations increase while ascending a high elevation becomes

[1] The Home of the Eddas. S. Low, 1879.

[2] Consumption as a Contagious Disease. Ballière, Tindal & Cox, 1880.

clear when we take into consideration the fact that at the sea level a cubic foot of dry air contains about 130 grains of oxygen, while at an elevation of 6000 feet it only contains about 106 grains—nearly twenty-five per cent. less than the body is accustomed to breathe at or near the seaboard—therefore, in order to supply the wonted amount of oxygen to the body, the respirations must either increase in number or in extent. From all accounts it is very probable that respiration becomes accelerated only during the early period of exposure to such an attenuated atmosphere, and that subsequently this function becomes slow again because the air penetrates more deeply and completely into lung tissue but little utilized before.

That man does not suffer under such a deprivation of oxygen is evident from what we know to be true of his lung capacity under ordinary conditions of life. Prof. Mosso has recently proven experimentally that man possesses a lung capacity which is nearly one-fourth larger than the actual necessities of life at the sea level demand; hence by employing his whole lung capacity he can extract a sufficient amount of oxygen from this attenuated atmosphere without difficulty. And herein lies the secret why so many consumptives, and others with weak lungs, derive such a great benefit when they resort to a mountain climate. It may be trite, but it is nevertheless true, that all consumption practically begins at the lung apices, because these parts are habitually inactive. They are inactive because, in the first place, the bronchial tubes are so arranged that they conduct the air with greater facility to the base than to the apex of a lung, and, in the second place, because the lung is larger than necessary; hence the base, which is filled most readily, is filled first, and the apex, if at all, toward the end of inspiration. The apices, therefore, become the superfluous parts of the respiratory organs. It is quite different, however, when the body is immersed in a highly attenuated atmosphere. Every available space in the chest is now brought into requisition to furnish the needed amount of oxygen, the apices are called out of their lethargic state, and the alveoli are inflated, and if the infiltrated areas are not dispersed the surrounding alveoli are kept permeable, and so the disease is, at least, limited and called into abeyance.

This statement is corroborated by those who have had large experience in the climatic treatment of pulmonary consumption. Thus Ruedi reports[1] "that of 600 consumptives under his care at Davos, expansion of the thorax took place in no less than 584." Dr. Denison says[2] "the increased circumference of the chests of consumptives after undergoing the high-altitude treatment is shown in many of Prof. Weber's, as well as in my own, cases." Dr. Lindsay, in the work already quoted, states (p. 32) that

"Davos does not cure consumption by its sunshine, or the purity and dryness of its air (although these conditions undoubtedly coöperate in the beneficial effect), but mainly by the rarefaction of its air, which stimulates respiratory activity, promotes healthy expansion and soundness of tissue in the lungs, and hence aids them to resist the spread of morbid deposits."

So much, then, for the immunity which is afforded by mountain climates; but that which is of still greater interest to us is the fact that those who follow active employment are less liable to this disease than those who pursue sedentary and quiet occupations. Thus M. Lombard found

"in Paris, Geneva, Vienna, and Hamburg, that there are a greater number of persons leading a sedentary life afflicted with phthisis than of those leading an active life, in the proportion of 141 to 89. In the Brompton Hospital the relative liability was found to be 63 per cent. of indoor males to 30 per cent. of outdoor, and all the consumptive females followed indoor occupations. Dr. Guy found, in the close workshops of a printing establishment, the compositors, whose employment is sedentary, fell victims to phthisis in the proportion of 44 per cent. to 31½ per cent. of the pressmen, who, although breathing the same air and in every other respect subject to the same habits of life, differ only in the active bodily exercise which the press imposes on them; and among the same class of operatives the deaths from the same cause did not exceed 25 per cent. in those who use exercise in the open air." (Ancell.)

There can be no doubt, too, that those of our Indians who are still allowed to obey their roaming instincts of hunting and of fishing, or to follow their vocation of farming, which a number have, owe their immunity from this disease, which we know they possess, in great part, if not entirely, to the physical exercise which they obtain in this manner; while those who are subjected to the idle and improvident reservation life die rapidly from it, principally because they are deprived of their wonted exercise. This is of special interest to us here, because it has such a direct bearing on the main point at issue. Some of the former class of Indians, like the Pimas, for example, who may be called wild, although they are agricultural in their habits, are living in half underground huts with very little or no ventilation, yet, from all accounts, consumption is an exceedingly rare disease among them.

Thus far we have seen that, on the whole, those who occupy elevated habitations, as well as those who follow active exercise, are more exempt from the disease under consideration than those who live near the sea level or those who live a life of quietude.

[1] Climatic Treatment of Consumption. By Dr. J. A. Lindsay, p. 62.

[2] Rocky Mountain Health Resorts, p. 85.

In connection with this we will consider the influence of physical exercise on the lungs, and endeavor to ascertain how it affords protection against consumption. During physical exercise more oxygen is consumed by the muscles, and more blood and air circulate through the lungs than during rest. Just how much more air enters the lungs during activity than during rest can easily be estimated when it is known that during inactivity a man breathes 480 cubic inches of air per minute, and while walking at the rate of four miles per hour, or while tramping a treadmill, he breathes 2400 cubic inches, and if he walks at the rate of six miles an hour he takes in 3260 cubic inches of air per minute. The difference between 480 and 2400 cubic inches of air-capacity shows that during the exercise of walking even at the rate of four miles per hour, five times more lung surface is thrown into action than during rest; which proves very conclusively that bodily activity possesses a marked influence in determining the degree of lung expansion, and that under such conditions regions of lung will be called into service which are never fully reached by air during bodily rest.

This is in entire accord with what practically exists. Thus Darwin[1] says that the lungs in improved breeds of cattle, which naturally take little exercise and are domiciled much of the time, "are found to be considerably reduced in size when compared with those possessed by animals having perfect liberty," and Waldenburgh[2] states that the vital lung capacity is smallest in persons who lead sedentary lives, such as professional men, students, clerks, etc., and is greatest in those who follow active outdoor occupations, such as sailors, recruits, etc. Chassagne and Dally, in their joint work on the *Influence of Gymnastics on the Development of Man*, report that at the Military School of Gymnastics of Joinville-le-Pont, out of four hundred and one individuals subjected to gymnastic exercises for five months, three hundred and seven, or seventy-six per cent., showed an increase on an average of over an inch in the mammary circumference of the thorax. According to Dr. Abel, seventy-five per cent. of those who practise gymnastics in Germany experience an increase in the measurements of the chest. There can be no doubt that the principal reason why consumption increases with the advent of civilization is that everything in civilized life tends to produce physical inertia in our bodies. Walking is substituted by riding in carriages and in cars; manual labor is in great part replaced by machinery; active outdoor labor is supplemented by quiet indoor occupations—in fact, everything which tends to produce physical activity is exchanged for a life of ease and indolence. The American Indian, as has already been stated, is known to be comparatively free from the disease in his wild state, but as soon as he acquires the habits and customs of civilized life he becomes its victim.

In converging the two lines of reasoning which have been thus far developed in this paper, it appears that the immunity from consumption which is established by residing in a mountain climate, and by practising physical exercise, is chiefly brought about in the same manner, viz., by increasing the capacity of the chest. And from a practical point of view it is of some moment to know whether the former has more weight in bringing about such restoration than the latter—or, in other words, whether those who live in high altitudes continue to enjoy this exemption if they refrain from active physical exercise and take up a sedentary occupation in such regions. From recent inquiry into this subject, we are inclined to believe, at least so far as the Rocky Mountains climate is concerned, that as soon as outdoor pursuits are exchanged for sedentary indoor occupations, consumption increases in frequency. It is, therefore, quite certain that physiological exercise plays a more important part in the problem of the prevention and cure of consumption than a residence in an elevated or mountain climate, however valuable the latter may be. We have, moreover, good reason for believing that the immunity which is established through physical exercise is more permanent in character than that which is secured through residing in a mountain climate, for it is a common observation that consumptives flourish only in high altitudes so long as they remain; a protracted stay at the sea level is always regarded as perilous. Such consequences are in perfect harmony with what one would be led to apprehend from a knowledge of the physiological factors involved in the restoration of the patient. These factors are entirely local, and their influence does not extend very far beyond their immediate dominion. This objection does not hold good in regard to physical exercise. One thing may be said, however, in favor of mountain climates which is not true of physical exercise, viz., it produces its beneficial results without conscious effort on the part of the individual; therefore, when the remedy is viewed from a standpoint of ease and comfort, and not from one of permanence, the mountain climate is to be preferred.

In discussing the influence of mountain climate it must not be overlooked that, on account of its rarefaction, it increases the circulatory and cellular activity of the body, and in this way undoubtedly aids the process of nutrition; yet even this influence cannot be denied to physical exercise, although it is brought about in a more direct and positive manner.

While increased chest capacity is, therefore, the great desideratum in preventing and treating con-

[1] Animals and Plants, vol. ii. p. 361.

[2] Pneumatische Behandlung Respr. u. Circul. Krankheiten, p. 119.

sumption, we have the strongest evidence for believing that it is not so much a question of developing the base of the lungs as it is one of expanding the apices. This is well shown by the fact that the civilized female, although she has, on the whole, much less chest capacity than the male, yet, owing to her increased costal expansion, which has been cultivated through the protracted influence of tight lacing, she is less liable to pulmonary consumption than the male.[1]

Pulmonary gymnastics.—Such, then, are the comparative effects of mountain climate and of physical exercise in the treatment of pulmonary consumption, and it now remains to be shown how the effects of the latter can be obtained without resorting to those of the former. Reference has already been made to the fact that muscular effort increases respiratory motion, and in taking up the question of pulmonary gymnastics it is not our purpose to discuss those exercises only which have a direct influence on the chest capacity, but also those which, through the body, have an indirect influence on the pulmonary organs. In all exercises it is very important that none should be carried to the extent of decided fatigue; and that, whenever possible, the body and head should be kept erect, the shoulders thrown back and the lungs thoroughly filled with each breath; that breathing should only take place through the nose; and that sufficient food is taken during the intervals.

Bodily exercise.—The power of walking is common to most people, and its influence on the lungs, as we have seen, is very marked. It is regarded of great service even by those who exclusively advocate the utility of high altitude treatment. Dr. Brehmer, of Görbersdorf, according to Schreiber, was the first to prescribe for consumptives, walking up a gradual ascent. A semi-daily walk of half an hour or an hour, either on the level or on a slight upward grade, is of immense advantage to the invalid. Running, dancing, skipping rope (especially when the rope is swung backward), bowling, etc., are to be highly recommended. Whatever the mode of exercise may be, it must be performed under as little compulsion as possible. One reason why the above-named exercises are so conducive to health consists in the fact that the excitement which they induce is so attractive that the consciousness of muscular effort is lost.

Among the many indoor exercises the following movements are very valuable. The arms, being used as levers, are swung backward as far as possible on a level with the shoulders during each inspiration, and brought together in front on the same level during each expiration. Or the hands are brought together above the head while inspiring, and gradually brought down alongside the body while expiring. When a deep inspiration is taken in accordance with either plan and held until the arms are gradually moved forward or downward, or even longer, the process of chest expansion is materially enhanced.

Another very effective exercise is to take a deep inspiration, and during expiration only the patient, in a loud voice, will count as long as possible. A male person with a good chest capacity can count up to sixty or seventy, while in a female with ordinary lungs this power is somewhat reduced. Practice of this sort will gradually develop the chest, and the increased ability to count is a measure of the improvement going on within the thorax.

Many of these movements may have their effects greatly enhanced by the use of dumb-bells, chest weights, etc., which are made especially for the purpose.

Compressed and rarefied air.—The breathing of compressed and rarefied air is attracting wide attention at the present time in connection with pulmonary consumption, and is another most useful method whereby the chest capacity can be markedly improved. Nearly four years ago Dr. J. Solis-Cohen advocated the substitution of compressed and rarefied air for a change of climate, in a paper which he read before the American Climatological Association. Here he says:

"In many cases fully as much good can be secured by this treatment as by change of climate, and in a few much more; though, in the vast majority of cases in which change of climate is advisable, it is but a poor substitute."

There can be no doubt that compressed and rarefied air is inadequate when used alone in many cases, but when combined with pulmonary gymnastics and other judicious treatment, we are not sure that the results obtained are inferior to those which are derived from climatic treatment. Recent experience has shown us that when consumptives, who had spent one or two winters on the Rocky Mountains, or on the Pacific Slope, without benefit, were subjected to the use of compressed and rarefied air in association with other pulmonary exercises, such as are above described, their improvement became marked and decided. On the whole, our experience with the air treatment, combined with pulmonary gymnastics, has been very favorable, and we think that this is in consonance with the observations of others. Thus the late Prof. Flint, in his work on *Phthisis*, says (p. 406)

"it does not appear, from the analysis of my cases, that changes of climate have in a marked degree a beneficial influence, as compared with the hygienic measures available at home."

We believe, however, that, as a rule, these measures are applied too infrequently to be of the greatest

[1] Female Dress as a Determining Factor in Pulmonary Consumption. Thomas J. Mays, M.D.: Medical News, January 7, 1888.

service; and, therefore, insist that the pulmonary gymnastics be repeated every hour and a half during the day—the first thing in the morning and the last thing at night—and for from fifteen to twenty minutes at each time; and that the air inhalations be given at first twice, and in the course of two or three weeks gradually increased to four or five times a day, and even oftener. It is very true that this method of treatment involves more labor and perseverance on the part of the patient than is required in a high mountain climate; but then it is a question whether the patient is not more than compensated by the consciousness that a separation from friends is unnecessary, that the heavy expense, the dangers and discomforts incidental to travel are avoided, and, above all, that the improvement which may take place will be persistent and be practically unaffected by a change of residence.

Now, after reviewing the whole subject, we are driven to the conclusion that the line of immunity from consumption, which, in the early history of our country, was located at the Atlantic seaboard, and which has gradually receded westward with the tide of civilization, until at present it has reached the latitude of Colorado, will not stop in its course until it touches the shores of the Pacific; that the question of curing the disease does not depend on the purity or freshness of the air, or upon the number of bacilli which the atmosphere may contain, or upon the amount of oxygen which may be introduced into the body—for these are all secondary considerations; but it is simply a mechanical question, a question as to the best mode of expanding the lungs, and especially the apices of our round-shouldered and flat-chested patients, of removing the infiltrated products already existing, and of enhancing the constitutional resistance.

MEDICAL PROGRESS.

Sarcoma of the Tonsils Removed by External Incision; Recovery.—Richardson, Surgeon to the Massachusetts General Hospital, reports in the *Boston Medical and Surgical Journal* of February 23, 1888, the following interesting case: Mrs. E. H., aged sixty, came from New Brunswick to the Massachusetts General Hospital, April 9, 1886. She said that she had noticed a swelling back of the angle of the jaw on the left side for two years. It was of slow growth, except that it had seemed to increase rather more rapidly for a short time before coming to the hospital. Externally there was only slight deformity, a small swelling being visible under the left ear. Internally the left tonsil was pushed with the pharynx quite to or beyond the middle line. The appearance of the mucous membrane of the pharynx was normal. The growth was indurated and could be felt under the edge of the jaw from the mastoid process half-way to the chin.

April 13, 1887, the tumor was removed by an incision three inches in length along the anterior border of the sterno-mastoid muscle. A careful dissection was made to get under the parotid, behind which the new growth was found encapsulated. The tumor was lobulated, and had finger-like projections running in various directions. It partly surrounded the styloid process and was attached to it, and from there extended inward to the middle of the pharynx. It was covered in the throat by the mucous membrane alone. A large portion of the tumor was shelled out, and the rest removed by dissection. The portion projecting into the pharynx was thoroughly removed, leaving nothing but the mucous membrane of the pharynx between the fingers when one was in the pharynx and the other in the wound. The tumor was situated in the place of the left tonsil. It was impossible to say either from the location or the microscopic examination whether the growth started in the tonsil or directly adjacent to it. There was no tonsillar structure discovered by the microscopic examination, or at least none reported. In effect, however, it was a tumor occupying the tonsillar region and interfering with deglutition and respiration. The upward growth of the mass in and between the pterygoid plates, and its attachment to the base of the skull made its complete removal very difficult, and the probability of return very great. After the operation there was very little venous oozing from the deep parts, which was controlled by pressure. The wound was closed with silk and drained. Corrosive sublimate irrigation, and iodoform gauze dressings. During the evening the throat became swollen and ecchymosed on the left side, causing slight dyspnœa. The pressure on the outside was therefore removed. The next day the ecchymosis had extended to the frænum of the tongue and down on the neck. There was paralysis of the left lower lip.

Three days after operation she could eat and talk without trouble. Dressings changed to phenyl pad on account of slight suppuration along track of tube.

April 29th: Throat normal in appearance.

May 5th: Discharged.

November 23, 1887: A letter received from the husband states: "She got quite well in three weeks' time, and has not felt any effects of it since, and her health is good." Microscopic examination of the tumor made at the Harvard Medical School was to the effect that it was a round-celled sarcoma.

The Treatment of Cholera Infantum by Oxide of Zinc.—Dupré reports good results from the following formula:

Zinc oxide	grs. 53.
Sodii bicarbon.	grs. 23.
Tinct. rhatan.	gtts. 20.
Syrup. simpl.	℥ 7½.—M.

Sig. A small teaspoonful every half hour until vomiting and diarrhœa are relieved.—*Revue de Thérapeutique*, Feb. 15, 1888.

Leiter's Improved Cystoscope.—Fenwick, in the *British Medical Journal* of February 4, 1888, reports that he has used the new instrument successfully. He concludes that the cystoscope will become rapidly popular, and be largely employed in the diagnosis of urinary diseases, may be argued from the simplicity, safety, and success of the instrument; but it is indeed difficult to predict accurately its future rank. It will obviously replace the large

collection of instruments or procedures which attempt the diagnosis of the source of hæmaturia and pyuria; for the ureteral orifices are clearly exposed to view. Its use will tend to limit the size and number of vesical papillomata by enabling us to detect and remove these and other growths in their very infancy. It will, moreover, afford us a clearer insight into the physiological and pathological conditions of the vesical mucous membrane, and allow us to control our clinical observations and speculations by direct visual research.

Calomel Hypodermatically for Syphilis.—Neumann, of Vienna, uses successfully:

Calomel,	
Sodii chlorat.	āā 1 part.
Aquæ destill.	10 parts.

The average dose of calomel is 1½ grains; a quantity of the mercurial always remaining in the syringe.

Neumann treated thirty-six cases, in five of whom relapses occurred.

He considers it much inferior to the method by inunction.—*Deutsche medicinische Wochenschrift*, February 2, 1888.

The Treatment of Chronic Pharyngeal Catarrh.—Endler, has used the following gargle with advantage:

Zinci sulphat.	1 part.
Aquæ menth. piperit. . . .	200 parts.

In very sensitive patients a 2½ per cent. solution may be used.—*Berliner klinische Wochenschrift.*

Rectal Alimentation in Children.—Jacobi, in the *Archives of Pediatrics* for February, 1888, advises as follows: The rectum absorbs, but it does not digest. Whatever, therefore, is to enter the circulation through the lower end of the alimentary canal must be dissolved before being injected. Suspension alone does not usually suffice. Water can be introduced in quantities of from twenty-five to one hundred grammes (one to three ounces) every one, two, or three hours, and may thus save life by adding to the contents of the thirsty lymph-ducts and empty bloodvessels. Salts in a mild solution will thus be absorbed. Food must be more or less peptonized before being injected. The peptones mentioned above are readily absorbed when fairly diluted. When too thick they are not absorbed, become putrid, and a source of irritation. Milk ought to be peptonized. The white of eggs becomes absorbent through the addition of chloride of sodium. Kussmaul beats two or three eggs with water, keeps the mixture through twelve hours, and injects it with some starch decoction. The latter is partly changed into dextrin. Fat, when mixed with alcohol, becomes apt to be partly absorbed. Andrew H. Smith recommends the injection of blood. Its soluble albumen, salts and water are readily absorbed: more we ought not to expect. Still, he has observed that the evacuations of the next day contained none of the injected blood. Whatever we do, however, and be the rectum ever so tolerant, not more than one-fourth part of the food required for sustaining life can be obtained by rectal injections, and inanition will follow, though it be greatly delayed. Finally, children are not so favorably situated in regard to nutritious enemata as adults. In these the lengthening of the nozzle of the syringe by means of an elastic catheter permits of the introduction of a large quantity of liquid;[1] indeed, a pint can be injected, and will be retained. But the great normal length of the sigmoid flexure in the infant and child, which results in its being bent upon itself, prevents the introduction of an instrument to a considerable height. It will bend upon itself; besides, a large amount of contents will be expelled by the feeble or resisting young patient.[1] When a solid instrument is used, it is apt to be felt high up in the abdomen. This is the result of a large portion of the intestine being pushed upward with the tube.

Glycerin and Cocoa Cream.—The *American Druggist* recommends the following formula:

White wax	℥xiv.
Spermaceti	℥iij.
Cocoa butter	℥ix.
Castor oil	℥ix.
Oil of benne	℥vi.
Melt and mix; then add glycerin . .	℥ij.

Perfume to suit taste.

This makes a nice preparation. Petrolatum is used instead of the oil of benne (sesame oil) by some, and is considered an improvement. Either, however, will do.

A Safe Solution of Nitroglycerin for Medicinal Use.—The *American Druggist* has consulted the Chief of the U. S. Torpedo Station at Newport, regarding the solution of nitroglycerin which may be safely used by physicians; the conclusion is as follows:

It has been repeatedly stated that a 10 per cent. alcoholic solution of nitroglycerin is non-explosive, but, so far as the pharmaceutical public is concerned, this information was not known (or known to but few) to be absolutely reliable. Prof. Munroe expressly states that this statement is correct, such a solution being *absolutely non-explosive.*

Salol in Diarrhœa.—Eichberg reports in the *Cincinnati Lancet-Clinic* of February 25, 1888, his results in the use of salol, as follows: During the summer I had employed the drug in a number of cases in which diarrhœa was, at one time or another, a prominent symptom. As will be seen, this symptom depended on most diverse conditions, as tubercular ulceration, dysentery, enteritis, or the simple diarrhœa resulting from errors of diet. The report embraces fourteen cases, of which two were cases of dysentery, four of diarrhœa, one of loose bowels accompanying chronic gastritis, four of phthisis with diarrhœa, one of enteritis, one of tertiary syphilis, one of diarrhœa with subacute Bright's disease. An examination of the histories attached to this paper brings out clearly the fact that salol, while of some service in diarrhœa arising from almost any cause, cannot be relied upon with the same firm faith with which we administer the preparation of opium. It seems to act promptly enough, especially in the simple forms of bowel trouble; but the antiseptic effect seems to pass off with some rapidity, so that it often becomes necessary later on to resort to other remedies.

[1] The amount can be somewhat increased by raising the baby by its feet, while the chest and abdomen are supported by a soft pillow, and injecting quite slowly, or, rather, allowing the liquid to flow in from above downward. Gentle manipulation of the abdomen, while the procedure is going on will aid our purpose.

The weight of this experience, therefore, is rather against than for its use.

At the outset it was always administered alone, without other medicines, so that its effect might be thoroughly tested; and, while I should be willing to give it another trial, I should not express any confident hopes of success for its use. It may be that the quantities given were too small, the average dose being ten grains repeated every four hours (lately this medicine has been administered in maximal doses of from forty to sixty grains at one time), and the result might have been different but for this factor; further experience alone can answer this point.

As compared with naphthalin, the advantage rests entirely with the latter drug, which on account of its comparative insolubility and slow absorption, continues to act along the entire intestinal tract, while salol being decomposed high up in the intestine and absorbed at once, probably does not reach the lower part of the canal in sufficient quantity to be of any service.

Fracture of the Skull; Cerebral (Cortical) Abscess; Drainage; Recovery.—At a recent meeting of the Society of German Physicians of Prague, BAYER reported the case of a workman who sustained, from machinery, a multiple fracture with depression of the left parietal bone. On the supervention of aphasia, facial paralysis, incontinence, and other symptoms of cerebral pressure, Bayer enlarged the original scalp wound, removed bony fragments with hammer and chisel, and found pus oozing through the dura. A cavity as large as an orange was emptied, the wound douched antiseptically, and dressed. Recovery, with restored functions, resulted, the aphasia disappearing last.—*Medicinische-Chirurgische Rundschau*, February 1, 1888.

The Contents of a Surgical Bag for Antisepsis.—EGLI-SINCLAIR, in the *Correspondenz-Blatt für Schweizer Aerzte* of February 1, 1888, states that but a few articles should be carried in a surgeon's bag, and those essential to antisepsis are soap, nail brush, and a preparation of bichloride of mercury, for which he gives the following formula:

Hydrarg. chlor. corros.	ʒ 10.
Aquæ dest.	ʒ 50.
Ammon. chlorat.	ʒ 2.
A vegetable coloring mixture . .	gr. 1½.

The stopper of the bottle in which this is carried is so arranged that by inverting it it becomes a measure, its contents added to one quart of water making a $\frac{1}{10}$ per cent. solution of sublimate, markedly colored.

The Treatment of Melancholia.—DEFOE has used the following pill with advantage:

Zinc. valerian.,	
Quin. valerian.,	
Ferri valerian.	āā gr. 15.
Mucilag.	q. s.—M.

Ft. pil. 20 in number.

Sig. One pill before the two heavier meals of the day. —*L'Union Médicale*, February 7, 1888.

The Value of Albuminate of Iron.—DUMONT, reviewing the literature of the subject, concludes that albumen conduces to the absorption of iron, when combined with it.

When administered iron takes up albumen at the expense of the tissues of the body. Albuminate of iron, prepared outside the body, is more readily assimilated than other preparations, occasions less frequently stomach disorders, and produces a rapid increase in the iron compounds of the blood.—*Le Progrès Médical*, February 14, 1888.

Constitutional Effects from Nasal Sprays of Cocaine.—WHISTLER, of the London Throat Hospital, reports that after a long trial limited applications of strong solutions of cocaine in the nose as a local anæsthetic do not, unless very exceptionally, produce general symptoms. Spray solutions of a strength not exceeding even four per cent. are more liable to do so, and should not, as a rule, be applied in greater quantity than ten minims, especially if used by the patient as a topical remedy in acute nasal catarrh; and then this application should not be often repeated. With such restrictions all risk of harm would be avoided. It is easy to foresee, however, that an agent which can exert the primary stimulating effects, which it has been found to do, would appeal to some; and that the unrestrained habit of resorting to nasal sprays of cocaine by patients may lead to deleterious results.—*British Medical Journal*, February 4, 1888.

Peroxide of Hydrogen in Diphtheria.—HATFIELD, of Chicago, in the *Archives of Pediatrics* for February, 1888, reports his experience as follows: During the past few weeks eighteen cases of diphtheria of varying intensity from very grave to light have been treated with hydrogen peroxide, and have given eighteen gratifying recoveries. The number of these cases is yet too small to draw general conclusions, but they have proven to the writer that in hydrogen peroxide we have an agent that is exceedingly valuable as a local disinfectant, when efficiently applied, either by means of a swab or in the form of a spray (two ounces diluted with seven times its bulk of water). Diphtheritic throats treated thus every two hours did not become, even in the worst of the eighteen cases under observation, putrid and offensive, as they invariably do if left to their own devices. Hydrogen peroxide does not act as a solvent upon the diphtheritic membranes, but rather as its disinfectant and antidote, nor does it prevent the formation for, but neutralizes the poison of, the diphtheritic exudate, and thus anticipates many of the sequelæ of this dread disease. The remedy is certainly worthy of more extended trial in malignant diphtheria.

An Incompatible Prescription.—VIGIER, in calling attention to the incompatibility of alkaloids and tannin quotes the following mixture, which resulted in the precipitation of the cocaine:

R.—Cocaine hydrochlorat. . . .	gr. 4.
Syrup. aurant. flor. . . .	ʒ 12½.
Inf. of blackberry-leaves . .	ʒ 25.

In this instance the tannin in the blackberry leaves was the precipitating agent.—*Gazette Hebdomadaire*, January 27, 1888.

Antipyrin in Nocturnal Emissions.—In a recent number of the *Wiener medicinische Blätter*, Dr. Thör, of Bucharest,

gives some particulars as to the effect of antipyrin in cases of nocturnal emissions. Lupulin and camphor had been justly abandoned in such cases. Curschmann ("Functionelle Störungen der männlichen Genitalien," in *Ziemssen's Handbook*, 1878, p. 418) states that the sedative effect of lupulin on the genital organs, in spite of all the recommendations, was not proved. As to camphor, it has, according to his opinion, no better effect. Fürbringer (*Krankheiten der Harn- und Geschlechtsorgane*, 1884, p. 347) is of the same opinion. Zeissl (*Syphilis*, 1882, p. 112) recommends it in the first place, as do Purgsz (*Recept-Taschenbuch für venerische Krankheiten*, 1883, p. 21) and other writers. The effect of nux vomica, arsenic, and atropine is also often uncertain. Among all the remedies hitherto employed, bromide of potassium or bromide of sodium was the most useful. Diday (*La Pratique des Maladies vénériennes*, 1886, p. 538) recommends it to the exclusion of every other drug. Bromide of potassium, from 30 to 75 grains in a glass of water, taken just before going to bed, will, according to his experience, exert a prompt effect and check the pollutions. The prolonged use of the preparations of bromine, however, as is well known, produced an acne-like eruption, and the use of the remedy had, for this reason, often to be discontinued. Dr. Thör states that he has found antipyrin an excellent substitute for the bromides. He gives it in doses of from 7½ to 15 grains, to be taken by the patient a short time before going to bed. In seven cases it had proved very successful, and checked the pollutions. No disagreeable after-effects were observed. In "neuroasthenia sexualis" in the sense of Beard (*Die sexuelle Neuroasthenie*, 1885) antipyrin could also be used with good results; but the dose had in these cases to be sometimes increased from 15 to 30 grains a day.—*British Med. Journal*, February 18, 1888.

A Case of Recovery from Subacute Phithisis.—Auld, in the *Lancet* of February 11, 1888, reports the following interesting case:

The subject of this communication, a woman, aged twenty-three, first came under my observation in the latter part of 1884. Her family history was bad: her mother and a brother had succumbed to lung disease; a sister was lying ill of phthisis, of which she shortly died; and she herself was weak, anæmic, and very dyspeptic.

Notwithstanding these hindrances, she managed, with the aid of arsenic and iron, to fulfil her arduous duties as a teacher, with but slight intermissions, until August, 1886, when increasing weakness, anorexia, and scrofulous inflammation of the right cervical glands laid her aside. An examination of the lungs at this time revealed nothing very definite. In due time a large quantity of characteristic pus was twice abstracted from the neck. Shortly afterward, about Christmas, an intense inflammation attacked the great joint of the thumb of the right hand, leading to sinuses, discharging evidently tubercular pus. After two months this discharge with its attendant phenomena began to disappear, while simultaneously were developed the signs and symptoms of phthisis pulmonalis.

The disease at first threatened a somewhat severe course. The left lung became extensively involved; temperature ranged from 102° to 104°; cough and expectoration considerable; night sweats profuse; circulation very weak; appetite gone. "Those are the gloomiest cases of phthisis," says Dr. Sutton, "where there are anæmia and weakness of the pulse." In the middle of May, Bergeon's treatment, then attracting attention, was contemplated, but the patient was considered too weak, and the idea was abandoned. About this time, however, the stomach, which hitherto had resisted all treatment, began to show signs of improvement, and as much suitable food as could be borne was administered. Occasional attacks of sickness were best relieved by a few drops of solution of cocaine, with ice, and the bowels were kept well open. No antiseptics were employed, as I have been invariably disappointed in their use. This improvement steadily increased, accompanied by a very pronounced amelioration of the general symptoms and a very remarkable gain of flesh, till by the middle of July the pyrexia and night sweats had almost entirely ceased. The expectoration nevertheless continued, and there were the physical signs of a vomica in the left apex, whilst in the right moist râles were audible. Considering the case unusual, I communicated with Prof. Hamilton, of Aberdeen, in the month of August, who kindly examined the sputum, and reported that, after a very careful examination, he found that "it contains the tubercle bacillus in considerable abundance." From this period onward the patient was rapidly recovering, and by the end of September the cough and expectoration had nearly ceased, the moist sounds had almost vanished, and vesicular breathing was partially restored over the damaged areas. Early in October menstruation took place for the first time in several years, the discharge being normal as to duration and amount. By the beginning of November the cough had entirely disappeared, no moist râles were audible, menstruation had reappeared, and hitherto this favorable condition is maintained.

Naphthalin in the Intestinal Affections of Children.—Widomitz is quoted by the *Medicinische-Chirurgische Rundschau*, Heft 1, 1888, in reporting the best possible results from the use of naphthalin in children. With the exception of dyspepsia, with vomiting of curded milk, he found it useful in all intestinal affections in the following mixture:

R.—Napthalin. pur.	. . .	gr. 5 to 15.
Muc. gumm. arab.,		
Aquæ chamom.	. . .	āā ℥ 10.
Ol. menth. piper.	. . .	gtt. 1.—M.

Sig. To be well shaken. Small teaspoonful every two hours.

Alcoholics may be added when the condition of the patient demands them.

Intestinal Obstruction, with Extra-peritoneal Rupture of the Colon.—At a recent meeting of the Clinical Society of London, Bennett reported the following case:

The patient was a gentleman advanced in age, who for many years had been habitually constipated. At frequent intervals he was in the habit of using violent purges, without which the bowels never acted. About the middle of September, 1887, the constipation became more obstinate, and attacks of colic, from which the patient had also often suffered for years, were frequent and most severe. He was able, however, to obtain sufficient relief by means of his usual medicines up to October 17th, when a very small hard motion was the

only result of his treatment; the colic, which was very acute, did not completely subside. Gradually the abdomen became distended, and great discomfort ensued in consequence. Further purges were taken without any good effect, although there was a frequent urgent desire to defecate. On the 21st, whilst stooping over a letter, he felt a sudden acute pain passing down into the left loin. Some nausea and faintness followed, from which he soon rallied. He was seen by Mr. Bennett on the 22d. His face was pinched and anxious in aspect. The tongue was brown and dry. The pulse very weak. The belly was much distended, especially on the left side, where the loin bulged very prominently. The rectum was empty, but a hard mass could be felt through its walls, situated in the bowel higher up. The distress from the distention was extreme, and the patient begged, for an operation. As the case was clearly one of obstruction above the sigmoid flexure, a left lumbar colotomy was performed. On opening the abdominal cavity there rushed out before any gut was exposed a large quantity of gas and some liquid feces. On introducing the finger the intestine could be felt in front of a space from which the gas, etc., had come; manipulation of the colon, which could be easily made out, caused the air which remained in it to come through an opening in the gut at the lower part of the space mentioned, just below which could be felt a hard mass in the bowel. The distention at once subsided, but the patient became collapsed and did not rally. The case was regarded as a clear instance of rupture of the colon outside the peritoneum, which explained the mildness of the symptoms following immediately upon the giving way of the gut, which it was assumed took place when the acute pain, mentioned in the account of the case, suddenly seized the patient. In the same way the one-sided character of the abdominal distention and the absence of peritonitis could be accounted for, and a curious corroboration afforded to a statement of the patient, to the effect that attempts at defecation only increased his distress, for it is easy to see how such attempts could force the contents of the colon more and more into the surrounding cellular tissue. The case was considered remarkable for its rarity, and on that account had been thought worthy of record.—*Medical Press*, February 15, 1888.

A Mixture to Replace Milk in Infant Feeding.—TEDESCHI used the following formula in 51 cases of cholera infantum, reporting 44 recoveries, 3 deaths, and the other patients unreported:

White of egg (dried)	ʒ 3¾.
Oil of sweet almonds	ʒ 8¾.
Sugar of milk	ʒ 10.
Carbonate of sodium	grs. 6.
Chloride of sodium	grs. 3.
Neutral phosphate of calcium	grs. 40.
Water	quart 1.

Of which an emulsion should be made.—*Revue de Thérapeutique*, February 15, 1888.

Antipyrin in Whooping-cough.—GRIFFITH, in the *Therapeutic Gazette* of February 15, 1888, reports fifteen cases of whooping-cough treated by antipyrin after Sonnenberger's method, which he describes as follows, his own results coinciding fully with those of Sonnenberger:

This author had under observation since 1884 two large epidemics of the disease at Worms; and becoming greatly dissatisfied with the usual methods of treatment, determined to experiment with antipyrin. As a check upon his results he treated some members of a family with this drug, and to others taken sick at the same time he gave quinine or chloral, or the bromides, or some other well-recognized plan of treatment. In other instances he administered antipyrin for a few days, then allowed an interval to pass in which no medicine was given, and finally returned to antipyrin. In a short time it became clear to him that this drug exceeded in value all others which he had yet employed for the malady in question; and he has continued to use it up to the present time—a period of two and a half to three years. He treated about seventy cases of the disease with antipyrin alone; giving it in doses of ½ of a grain in quite young children, up to 7 to 15 grains, for larger children or adults, three times a day; though he believes much larger amounts might be given.

A most important fact is that the best results were obtained when the course of treatment was commenced at the beginning of the disease. Under these circumstances the affection lasted in all but three to five weeks, and was of a mild character, with not more than six or seven slight paroxysms in the twenty-four hours. When it is remembered that an average case has, according to Eichhorst, twenty to thirty paroxysms in a day, while in a severe case the number may even reach one hundred, it will be recognized what an improvement this is. But even when the treatment was instituted at the acme, and with the most unfavorable hygienic surroundings, good results were obtained. The paroxysms often became less violent after the first dose, and after several days occurred less frequently. When the drug was stopped the symptoms grew worse, showing that the effect was actually due to its use. In only five cases did he observe complications, and there was no instance of antipyrin-collapse. It would seem, then, pure cavil to deny that in antipyrin we have a drug capable of influencing whooping-cough most powerfully, especially in the first and second stages, where other means so often fail.

Antipyrin may be given in

R.—Antipyrin.	ʒ 6.
Aquæ	ʒ 2.
Syrup. simpl.	ʒ ½.
Tinct. anisi	ad ʒ 3.—M.

Sig.—Fifteen grains to the teaspoonful.

For children:

R.—Antipyrin.	gr. 2½ to 8.
Syrup. aurant. flor.	ʒ 13½.
Aquæ	ʒ 25.

may be prescribed.

By rectal injection:

R.—Antipyrin.	gr. 30.
The yolk of one egg,	
Warm water	quart 1.

In suppositories:

R.—Antipyrin.	gr. 8.
Ol. theobrom.	gr. 60.
Cocain. hydrochlorat.	gr. 1½.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, MARCH 10, 1888.

ERYTHROPHLÆINUM OR HAYA.

UNDER this rather cumbersome name, a new local anæsthetic has been brought very lately before the profession by the Germans.

In the *Deutsche med. Wochenschrift* of January 19, 1888, is a note on its action by LEWIN, read before the Berliner medicinische Gesellschaft, in which he records the results obtained by dropping a solution of the drug in the eyes of cats, dogs, and rabbits. He found that anæsthesia came on in from fifteen to twenty minutes, and lasted as long as twenty-four hours. When given hypodermatically to the frog, the heart-beats became more rapid, but later were slowed, while, in the warm-blooded animal, weakness asserted itself, the head was drooped, and the creature soon lay down, relaxed and powerless.

The drug is derived from an African plant, the *Erythrophlæum judiciale*. Lewin used it in the form of a two-tenths of a one per cent. solution of the active principle, erythrophlæin.

In the *Wiener med. Presse* of February 5, 1888, NEVINNY records his experiences, many of the results of Lewin being confirmed by his work. In addition we have the researches of EGASSE, in *Nouveaux Remèdes* of February 8, 1888, in which the period of anæsthesia is stated to last from eight to ten hours.

When Egasse gave the drug hypodermatically to the frog, symptoms other than those already mentioned came on. Convulsions, preceded by persistent dyspnœa, and followed by paralysis, occurred, while loss of reflex activity, and finally of sensibility, were noted. Pigeons were also convulsed by it. Trials made by LIEBREICH and GOLDSCHMIDT, the results of which have been more recently published in the *Deutsche medicinische Wochenschrift* of February 16th, and the *Centralblatt für klinische Medicin* of February 18, 1888, are virtually identical with those of earlier investigators.

The drug in solution forms a dark, opalescent liquid, of an alkaline reaction and yellow color.

THE TENEMENT-HOUSE PROBLEM.

THE provision of comfortable and healthy homes for the poor of large communities is a problem of no easy solution. As shown by the last census, there is a steady movement of population from the country to the populated centres, and consequently the proportion of the inhabitants who live in the cities is steadily increasing. The urban population is also constantly increased by the arrival of immigrants, many of whom are without any occupation whatsoever. Those willing to work find greater inducements in the country districts, while the improvident and incapable are attracted by the wealth of the cities. This rapid increase of population has had a prejudicial effect upon the dwellings of the poor. The demand for accommodations has increased the value of house property, with the immediate effect of compact building, and overcrowding and its attendant evils. Under these conditions the tenement-house system has become established in most of our cities to meet a necessity which has arisen, and which, to a great extent, has been met before the authorities were prepared to regulate the construction and management of the buildings, and, consequently, tenement-houses have been erected with a reckless disregard of sanitary needs.

The evil has been of rapid growth, but it has not escaped the attention of philanthropists and legislators. The question of providing accommodations for the working classes in large cities has long been a matter of national importance in England, and many acts have been passed, such as the Towns Improvement Clauses Act of 1847, the Metropolitan Buildings Act of 1855, the Sanitary Act of 1866, and the Artisans' and Laborers' Dwelling Act of 1868, which regulate the construction of houses, the manner of occupancy, and provide for the sanitary supervision of the lodgings of the masses. This legislation has no parallel on this side of the Atlantic, because of the comparatively recent growth of the evil, and our limited experience and less extensive

opportunities for studying the tendencies of the housing movement, and developing plans for correcting its bad features. Progress, however, is being made in this direction.

A good idea of the position which the housing movement has attained in our great cities may be obtained by consulting the *Report of the Proceedings of the Fourth Annual Session of the National Convention of the Bureaus of Statistics of Labor in the United States*, held in Trenton, in June of last year.

As might be expected, the tenement-house system has shown its greatest development in New York City. There land is high, and the poor population large—two factors which lead to overcrowding. In order to relieve this condition, the Tenement-house Act of 1867 and subsequent amendments were passed. The earnest efforts of philanthropic citizens and the praiseworthy endeavors of the New York Improved Dwellings Association have done much to further the project for providing better accommodations for the poor. The marked progress in measures of reform noticed in that city within the past few years is largely due to these influences.

In Chicago the same progress does not appear to have been made. The rapid influx of aliens of every nationality and grade of society has overtaxed the supply of proper accommodations. Owing to this deficiency, the mixed population who inhabit the lower quarters are crowded into the rookeries without regard to health or decency.

In Philadelphia the evil of overcrowding has, in a great measure, been prevented by the provision of small houses for the working people. Tenement-houses are few in number, and are inhabited mostly by the idle and improvident. The great popularity and success of building associations and the cheapness of land have made individual houses available, and for these there is a decided preference. Individual enterprise, encouraged by this success, has also assisted in the movement.

The time is opportune for systematic investigation of the condition of the working people, with special reference to their house accommodations. Much useful information on this subject has already been collected by the bureaus of statistics of labor which have been appointed in a number of States. The societies for organizing charity, now widely established, are closely identified with this humanitarian work, and are capable of exerting a powerful influence in elevating this class of society by improving its surroundings. Practical results are to be derived from an extension of the plan of building associations, which has been so successful.

As the provision of improved dwellings for the working people, by conducing to morality, health, and thrift, is important, aside from its philanthropic objects, as a matter of civic policy and economy, the State has an obligation from which it cannot honorably escape. The State cannot build houses for the poor, but it can regulate their construction and management. Strenuous efforts should, therefore, be made to secure the legislation needed to regulate the construction and government, specially with regard to light, ventilation, number of occupants, size of open spaces, etc., of buildings for the accommodation of this particular class of the community.

DEATH OF PROFESSOR WAGNER.

Our exchanges announce the death of Ernst Wagner, Professor of Medicine in Leipzic, one of the best known and most esteemed of German physicians. He was born in 1829, and received his medical education in Leipzic and in Vienna under Oppolzer. He early became Wunderlich's assistant at Leipzic, Docent in Pathology, and in 1863 Professor of this branch. From 1868 he held the ambulatory clinic, and succeeded to the Chair of Medicine on the death of Wunderlich. His *Manual of General Pathology*, which was translated a few years ago, made his name very familiar to English students. From 1860 he edited the *Archiv der Heilkunde*, in which he published a long series of valuable pathological and clinical papers. Since its suspension his contributions have enriched the *Deutsches Archiv f. klin. Medicin*, and a few weeks ago we presented our readers with a notice of his paper on "Idiopathic Œdema."

Wagner was a model clinician, and as a teacher of medicine he had scarcely an equal in Europe. Devoted to the study of morbid anatomy, and passing daily, as a matter of routine, from the wards to the post-mortem room, he had acquired in the course of a long and varied experience remarkable skill in the diagnosis of disease. He was essentially a practical physician, a wise therapeutist with an enthusiasm judiciously tempered by an unusually accurate knowledge of the action of drugs in the different phases of disease. He was a good example of the type of man which has made German medicine famous. "Ohne Hast aber ohne Rast," day by day, in the ward, the laboratory, and the class-

room, the work was done with a painstaking care, which increasing years did not diminish. His death at a comparatively early age is a serious loss to the profession and a grievous one to the University of Leipzic.

Ever since the first appearance of epidemic cerebro-spinal meningitis in Philadelphia, in 1863, there have been sporadic cases reported, and, if we can rely upon the city mortality returns, not a year has passed without the occurrence of thirty to eighty deaths from this cause: while in the years 1864, 1865, 1867, and 1872–1873, the cases increased to epidemic proportions. Making every allowance for errors in diagnosis, the persistence of the disease seems well established, and as Dr. Stillé remarks, in his exhaustive article in the *System of Medicine* by American writers, "it would appear that the disease continues to linger in this locality longer than has been reported of any other place of which information has been obtained." Within the past few months there has been an increase in the number of cases, and deaths from the disease have occurred in Germantown, Chestnut Hill, and the Falls of Schuylkill. At a meeting of the Neurological Society last week, Dr. Mills referred to a number of cases which he had seen.

It is extremely desirable that an accurate record be kept of the cases as they occur, and of the local conditions under which the disease develops, as the careful study of small, limited epidemics may throw light on some of the obscure problems relating to the etiology of this most serious malady.

The preliminary programme of the First Congress of American Physicians and Surgeons has just been issued. The Congress will be held in Washington on the evenings of September 18th, 19th, and 20th of this year.

On the first evening a discussion on "Intestinal Obstruction in its Medical and Surgical Relations," will be opened by Dr. Reginald H. Fitz, of Boston, and Dr. Nicholas Senn, of Milwaukee.

On September 19th, a discussion on "Cerebral Localization in its Practical Relations," will be opened by Dr. Charles K. Mills, of Philadelphia, and Dr. Roswell Park, of Buffalo.

On September 20th, the President, Dr. John S. Billings, will deliver an address, which will be followed by a general reception in the United States Army Medical Museum Building.

The special societies forming the Congress will hold their separate meetings during the mornings and afternoons of the above days. The Association of American Physicians has issued a preliminary programme for its meeting, which will be found in another column.

The Seventeenth Congress of the German Surgical Society will be held in Berlin, from the 4th to the 7th of April, 1888.

The meeting will be preceded by a Memorial Celebration in honor of the deceased President von Langenbeck, held on the evening of April 3d, in the hall of the Philharmonic Society. Mozart's Requiem will be rendered, and a Memorial Address will be delivered by von Bergmann.

The Third Congress of French Surgeons will convene in Paris, March 12–17, 1888, under the Presidency of Verneuil.

The Obstetrical and Gynecological Society of Vienna has been recently organized under the presidency of Professor Breisky.

The medical friends of Dr. D. Hayes Agnew will celebrate the fiftieth anniversary of his entrance into the profession by entertaining him at dinner on April 6th. Later in the month the medical students of the University of Pennsylvania will give a reception at the College in commemoration of his Jubilee.

The Alumni of Bellevue Hospital Medical College have erected a tablet in the Carnegie Laboratory to the memory of the late Austin Flint, M.D., which will be formally unveiled this evening, and Dr. Leroy M. Yale will make the presentation address.

Dr. Allis will deliver the Mütter course of lectures on the "Surgical Pathology of the Articulations," on Tuesday and Friday evenings, at eight o'clock, beginning March 6th and ending April 6th, at the Hall of the College of Physicians of Philadelphia. The course is open to the Fellows of the College and the medical profession.

At the recently held Commencements the degree of M.D. was conferred on graduates in medicine as follows:

University of the City of New York, 163; Rush Medical College, Chicago, 132; University of Buffalo, 44; Meharry Medical College, Nashville, 18.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 1, 1888.

THE PRESIDENT, A. JACOBI, M.D., IN THE CHAIR.

DR. EDWARD B. BRONSON read a paper on the question

SHOULD WE TREAT SYPHILIS DURING THE PRIMARY STAGE?

The poison of syphilis, he said, having once been effectually inoculated, are there any means at our command by which we may hope to prevent the impending constitutional effects? By preventive treatment is not necessarily meant abortive treatment; but it embraces all measures tending in any degree to abridge or mitigate the subsequent course of infection, and its effects on the constitution. The utility of any such measures will depend, first, on what the nature or essential quality of syphilitic infection is; and second, on the special status of this infection during the primary stage of the disease.

But of syphilitic infection we have no positive knowledge, either as to what constitutes its essential element, or what is its mode of progress; so that until more light is shed upon this unsolved problem we must make the most of what there is. The question in the form in which it immediately presents itself, may be stated as follows: Are the indications thus far afforded by our imperfect knowledge of syphilitic infection such as to render any attempt at preventive treatment in the primary stage of the disease unavailing and absolutely hopeless, as is maintained by many?

There are two modes of approaching this question: one theoretical, and the other empirical. In considering the indications furnished by the pathological conditions in syphilis, the first inquiry is naturally directed to the essential cause of the disease. Here all is as yet hypothetical, and the most that we can do is to accept provisionally that view by which most is explained. No theory explains the observed phenomena of syphilitic infection so satisfactorily as that which attributes them to the presence and growth in the tissues of certain specific microörganisms. Thus far the microbe of syphilis has not been positively determined; but even were it fully established that syphilis is a parasitic disease, due to known forms of microörganisms which could be cultivated outside of the body, it is by no means certain that the answer to the question of the utility of preventive treatment would be affirmative. Judging from experience in such diseases as tuberculosis and contagious anthrax, in which the specific germ has been identified, the success of antiseptic treatment is far from assured.

But the conditions in syphilitic infection are peculiar. Not only does the inoculation usually take place at a single point where it is freely accessible to manipulative procedures, but there are indications in the slow and gradual progress of the disease that general infection does not take place immediately, but that there is a temporary sojourn of the virus in the region where first implanted. After the virus has been inoculated there ensues a period of apparent quiescence of several weeks' duration, when, little by little, there begins the formation at the inoculated point of a neoplastic, indurated growth, which essentially consists of inflammatory granulation tissue, answering in its general characters to an irritative lesion provoked by the presence of a foreign and disturbing element. Simultaneously with this "initial lesion" of syphilis, or shortly following its first appearance, the nearest lymphatic glands become swollen and indurated in consequence of a cellular growth of a corresponding character to that of the "initial lesion." These local manifestations remain for a considerable period the sole evidences of disease; till finally, at the expiration of this period, with more or less sudden onset, the symptoms of general or constitutional syphilis make their appearance. The most satisfactory explanation of this course of events is that when first implanted in the tissues the virus does not immediately pass into the general circulation, or what portion does is insignificant; that, mainly at least, it is at first confined to the spot where the future chancre is to develop; that here finding a favorable soil it grows and slowly increases till its intrusive presence becomes a source of offence to the tissue harboring it, and gradually inflammatory reaction results. From this source of generation the virus contaminates sooner or later the nearest lymphatic glands, which in turn become other sources of supply, until, finally, from these multiple foci the whole organism becomes infected. According to this view the main route to the general circulation is by way of the lymphatics, and through the *receptaculum chyli*.

To this Auspitz has objected, that within the initial lesion the lymphatics show comparatively little change, while the bloodvessels are commonly implicated, and often occluded; and that between the chancre and the *receptaculum chyli* the chain of indurated glands has not yet been shown to be continuous and complete. But that the lymphatics in the primary induration are but slightly affected may, perhaps, be the very reason why their absorbent function is not disturbed. The objection that the lymphatic chain is not continuous seems to be based mainly upon the pathological specimens in the *Musée de Lourcine*, described by Fournier, which were taken from cases in which it is not stated how long the disease had lasted when the patients died.

Thus far the pathological conditions seem to imply that the disease advances by way of the lymphatics in a manner analogous to the diffusion of the malignant tumors. Whether, however, in syphilis the contamination advances by such regular approaches from one gland to another that any definite interval can be said to exist between the infection of one gland and that of the next in succession is very doubtful. In the indications presented up to this point we find nothing incompatible with the position that during the primary period of syphilis the disease is localized within the vicinity of the point of inoculation; but the view is current among many syphilographers that the manifestations of this period are always anticipated by infection of the general system. According to this position, directly upon its inoculation, the syphilitic virus passes into the general circulation, and the incubation pertains not to any *materies morbi* in the vicinity of the point of inoculation, but to something in the blood; whilst the initial lesion is the first tangible sign of the blood disease, reflected in some arbitrary and inexplicable manner to the spot where the virus effected its original entrance.

Two facts are alleged concerning the primary stage of syphilis, upon which the theory of the symptomatic character of the initial lesion is based: (1) that an individual

who has been inoculated with syphilis has always acquired immunity from any subsequent inoculation of the syphilitic virus before the chancre develops; and (2) that extirpation of the chancre does not prevent the regular course of the disease. That there is a period within a certain time after inoculation when the tissues are not refractory to a second implantation of the virus is shown by the fact that when a second or a third inoculation takes place within a short period from the first exposure, successive and multiple chancres result. The immunity, therefore, is not established at once. But it is claimed that after the chancre has once formed constitutional infection is an accomplished fact, and immunity is then complete. In verifying this point, however, the length of time it requires for the chancre to develop should be taken into consideration. The second inoculation might have its effects forestalled and prevented by constitutional infection intervening before the completion of its incubation. While it is true that, as a general rule, auto- and re-inoculation in the primary stage fail to produce any perceptible effect, a sufficient number of cases have been reported to show that the rule is not invariable, and that if immunity be the test of general saturation with the syphilitic poison, we must conclude that the chancre is not positive evidence of consitutional disease, and hence cannot be its symptom.

It may be conceded, however, that in the majority of cases immunity does precede what is known as secondary syphilis. It seems not improbable that a slight degree of general infection may exist in primary syphilis, which, though sufficient to confer immunity upon the individual from any second instalment of the virus, is not insufficient to cause general disease. A notable illustration of such an immunity is shown in the case of the mother of a syphilitic child, who, notwithstanding she may at no time present any outward sign of syphilitic infection, is immune from contagion, and suckles her child with impunity. Moreover, there is nothing in the view proposed that does not accord with the results of preventive inoculation in other infectious diseases.

The results of ectrotic treatment have thus far afforded but little encouragement. It is affirmed to be the rule in infectious diseases generally, which take their origin from a local point of inoculation, that it is impossible to prevent general infection. In syphilis, however, all the obvious signs point to a much slower development than in the others. Certain results reported by Sigmund, of Vienna, would seem to be clearly in favor of abortive cauterization immediately after syphilitic inoculation. Of 57 patients who presented themselves with abrasions after suspicious connection, 35 were cauterized, and of these only 10 developed syphilis. Of the 22 not interfered with, 11 became syphilitic. There were also indications that the earlier the cauterization was practised the better the chance of its success. Thus, of the 35 cases cauterized, in 24 this was done from the first to the third day following the suspicious exposure, and of these only 3 became syphilitic. Of 11 cauterized from the fifth to the tenth day, 7 became syphilitic; and this would tend to show that after the fourth day the chances are against the success of the operation.

Most discouraging is the well-known case reported by Berkeley Hill, in which a patient with a torn frænum, who was cauterized twelve hours after a sexual encounter, returned a month later with the cicatrix indurated, and afterwards developed constitutional syphilis. A possible loop-hole of escape may be found in the supposition that the patient had exposed himself to the disease during his month of absence. Still, there is evidence enough to show that the virus of syphilis passes beyond the reach of caustics within a short period after its inoculation. *A fortiori*, by the time the chancre is developed, it should be still further removed. But though inaccessible to caustics, it has been hoped that the infected part might be included in a free incision, and while the results reported have shown a most exasperating diversity, the fact remains that in a considerable percentage of the cases the occurrence of constitutional syphilis was apparently prevented.

It cannot be said, however, that the results of excision make conclusively either for or against the hypothesis of the local character of primary syphilis. As a manifestation of primary syphilis, the chancre is hardly of more importance than the indolent adenopathy. That the indurated lymphatic glands in the vicinity of the initial lesion are contributory sources of infection, there is little reason to doubt; and were the initial lesion removed they would, doubtless, still suffice to contaminate the system.

While, then, it cannot be affirmed of any period in the course of the malady that the disease is strictly limited to the site of the initial lesion, the proposition that syphilis is essentially a local disease, remains still uncontroverted. As to the hope of preventive interference afforded by the views now presented, it was intimated at the outset that the answer to the question might be equally valid whether based upon theoretical or empirical grounds. Empirically, the answer is so ambiguous that we have been forced to have recourse to theory; and here we find the omens not unpropitious. An infection whose limits are circumscribed, and more or less definable, is a very different thing to one that has already taken possession of the entire organism. During the forty days sojourn of the enemy in its outlying camps, while the insidious infection is slowly advancing its outposts from the periphery to the vital centres, are there no other resources than in excision of the initial lesion, which is but one of the multiple foci of infection, or this, together with extirpation of a few inguinal glands, and in constitutional treatment?

Excision of the initial lesion may have accomplished something. Certainly, when practicable, it is a perfectly rational, safe, and proper surgical procedure. It is removing an annoying symptom, and a possible source of danger to others. In a few instances, excision of inguinal glands, together with the initial lesion, has been reported, but thus far without noteworthy result; though it is by all means desirable that experiments in this direction should be continued. Inspired by the success of Pasteur in his preventive inoculations for charbon, it occurred to Diday that by inoculating a patient recently infected with syphilis with an attenuated syphilitic virus, the course of the disease might be prevented. This idea has never been put in practice, so far as known, but the field of investigation it suggests is an attractive one.

As to the value of medicinal antisyphilitic treatment during the primary stage, there is a diversity of opinion. While it is pretty generally conceded that the employment of mercury in this stage tends to retard the appearance of constitutional symptoms, the apprehension has been expressed by some that in repressing the outward

manifestations of infection we are risking a more serious implication of internal organs. There is an inconsistency, however, in the idea that for the month or so of primary syphilis that same remedy is to be shunned, because of dangerous after-effects, whose continued employment during the years of the constitutional disease is accepted without demur. In how many instances do we administer mercury internally in syphilis for strictly localized lesions; where the general system shows no sign of the disease, and with unquestionable effect. There is hardly any one but admits that when the chancre is formidable in size, or slow in yielding to local measures, a mercurial course will hasten its involution. It must be granted though, that it is taking a very roundabout road to reach the result.

Supposing that mercury does act as an antiseptic in syphilis, it is very questionable whether it could have any effect upon germs circulating in the blood; and it is much more probable that the effect would be exerted where both the germs and the mercurial would be apt to accumulate, as at such places of elimination as the skin, or where deposited in the tissues. That mercury does exert a most decided influence upon the local manifestations of syphilis when topically applied we have undoubted evidence; then why should not this potent influence be brought to bear directly upon those local lesions which are also dangerous foci of infection in the primary period of the disease? It is only recently that the so-called "regional treatment" of primary syphilis has received much attention; nor have any remarkable results as yet been reported. Dr. Bronson said that his own experience has been mainly confined to certain experimental attempts as to the feasibility of the method. It was, therefore, almost purely on theoretical grounds that he recommended this treatment.

The scheme consists in the local use of antisyphilitics by a method designed to bring the remedy in direct communication with the whole of the affected region in primary syphilis, including more particularly the initial lesion and the diseased glands. As commonly employed, the regional treatment has consisted chiefly in the use of mercurial hypodermatics beneath the initial lesion (except this lesion be excised), and into the mass of the indurated lymphatic glands. But the plan may be easily extended. The field of operation may include all of that district whose lymphatic vessels tend in their course toward the ganglia which are the seat of the disease. When the initial lesion is situated upon the genitals the area most available would consist of the external genitals, the perineum, and the upper inner and anterior aspect of the thighs, together with the inguinal region and lower part of the abdomen. By multiple small injections and by inunctions within this area the remedy may be introduced little by little into the lymphatics, with the hope of its being conveyed in sufficient amount to the diseased glands to destroy the infectious germs or to retard their multiplication.

The only agent thus far employed for this purpose is mercury. No substitute for it has been found, and the question is how to introduce this irritating agent into the affected region with the least amount of offence to the normal tissues, but in sufficient quantity to exert its antidotal or antiseptic influence upon the germs of the disease. Where hypodermatics are used it is not necessary that the drug be injected in large quantity in any one spot, nor in a concentrated form. A twentieth of a grain, or less, of the bichloride introduced in separate injections of not over a hundredth of a grain each would afford a more reasonable hope of effectively reaching the seat of the disease than a much larger dose given by the mouth. Dr. Bronson has used a solution of 1 part in 400 or 500 of mucilage and water, with a small quantity of common salt added. Of this, four or five injections are made of four or five minims each, distributed over different parts of the cutaneous area above described. The discomfort caused by the injections is insignificant, especially if care is taken to avoid any escape of the fluid into the corium. The number and frequency of the injections must depend on circumstances and on individual judgment. Into the skin of the abdomen and thighs they may be repeated daily, or every second or third day. Together with these injections, but more especially in situations where the latter are less admissible, as in the perineum and over the penis and scrotum, inunctions also may be employed; and for this purpose a mercurial soap will be found preferable to the mercurial ointment. Many modifications of the plan thus outlined will doubtless suggest themselves. It may be said that regional treatment is also constitutional treatment, as in a degree it doubtless is; but it is something more, and surely it is something better than doing nothing at all.

DR. EDWARD L. KEYES said that Dr. Bronson apparently advocated the proposed method of treatment purely on theoretical grounds, and he regretted that there had not been some practical results to show. It seemed to him, since the complete excision of the initial lesion did not materially modify the subsequent course of the disease, that when the latter has once shown itself the infection is already beyond the reach of any local treatment. His impression had always been that the disease becomes general from the time it is acquired, before the appearance of the primary lesion, which occurs only after a period of incubation. He believed, therefore, that the virus at once got beyond the lymphatic chain. A case was then related in which, notwithstanding the complete excision within twelve or fifteen hours after a suspicious connection, of a small livid papule on the back of the penis which resulted from the latter, the most marked constitutional symptoms subsequently occurred. In this instance there was no further trouble whatever about the local lesion, and not the slightest enlargement of the inguinal glands. Dr. Keyes also referred to Berkeley Hill's and other cases as corroborative of the assumption that the infection is already beyond the lymphatic glands before the appearance of the initial lesion of the disease. Whether washing the parts immediately after suspicious contact would have in any case the effect of preventing infection of the system he could not say.

He went on to say that he hoped Dr. Bronson would follow up the investigation; but the objection to local treatment with the only agent that is of any service afterward, before the diagnosis of syphilis is established, consisted in the fact that such a course is always likely to throw more or less discord into the life of the patient. He also related the case of a student of Bellevue, who, contrary to his advice, commenced a mercurial course in consequence of a slight abrasion of the prepuce. At the end of six months, no evidence of syphilis having in the meanwhile presented itself (with the exception that a

single one of the post-cervical glands became enlarged), he gave it up. Within two years, however, he became the subject of hemiplegia, and eventually died of syphilitic brain disease. As a rule, he believed it is much better to delay treatment until the diagnosis is comfirmed by the appearance of secondary symptoms. Otherwise a patient might be treated for syphilis who did not have the disease at all; and he had known of one instance in which a gentleman who never had the disease took bichloride of mercury for twelve years in consequence of a mistake of this kind.

DR. ROBERT W. TAYLOR said that he agreed with Dr. Bronson that the history of the disease and the analogic evidence afforded by certain other infectious diseases showed that syphilis is at first a local affection. The hyperplasia caused by the virus inoculated resulted in this initial lesion; but a very extended experience had convinced him that neither excision nor cauterization would prevent constitutional infection. Dr. Bronson's idea was certainly a most laudable one; but there is already enough evidence to show that syphilis cannot be exterminated at the radicles. Bloodvessels are frequently found running up to the chancre, and the new-growth cells germinate indefinitely; so that he did not believe that a single case of true syphilis had ever been aborted. He thought that Dr. Bronson was wrong in regard to the mother of a syphilitic infant. It is well known that Collis's law has been generally accepted; but while it is true that a woman can have a syphilitic child and yet not take the disease herself, it is a fact, as shown by Caspari, that she may contract the disease in the regular way.

In discussing inguinal treatment in primary syphilis, Dr. Taylor went on to say we must remember that the circumstances are entirely different from what they are later on. We then have to deal with a nascent disease which exhibits remarkable activity, and hence the most powerful remedies are required to destroy the new growths that are forming. Larger doses of mercury would be necessary to do any good; but we cannot employ the agent in the degree of concentration required, and it is, moreover, impossible to use the bichloride hypodermatically about the legs without producing abscesses.

He agreed with Dr. Keyes that it is most rational to begin the treatment with the secondary stage of the disease. By so doing a more orderly sequence is secured, and the moral effect upon the patient is also much greater when the secondary eruption appears to become at once tractable, a result which in many instances cannot otherwise be attained. There are, however, certain conditions which call for early treatment, and among them are the following:

First. When the chancre is so large as to impede urination; when there is phagedena; and when the chancre is situated about the eyes, mouth, or fingers, where it is liable to give rise to the infection of others.

Second. Where there are social reasons that the true nature of the trouble should be concealed, if possible.

Third. In the case of syphilo-maniacs.

As far as we can judge, mercury acts by causing fatty degeneration of the syphilitic cells, and as these cells do not become matured until the constitutional symptoms of the disease appear, it is highly irrational to use this agent until the secondary stage is reached, since syphilis does not run the tractable course in those who are treated early as in those from whom mercury is withheld until after the primary stage.

DR. BRONSON said that as to the charge that his views were founded on mere speculation, he held that it was necessary that the subject should be approached in a speculative spirit. What he had endeavored to do was to point out the indications which calls for early treatment. If the disease was primarily constitutional, there were no such indications. But the fact that the disease was primarily local did not imply that excision of the initial lesion should abort it. In his argument he had expressly discarded excision as a means of abortion, because by the time the chancre appeared the disease had advanced to the lymphatics. In order to abort it it would be necessary that all the foci of infection should be eliminated, and this has been proved to be impossible. Believing, however, that the disease was still local, he thought it was the duty of the surgeon to treat it regionally and thus counteract the infection as far as possible. The objections that had been urged to this course seemed to him altogether trivial, and he felt confident that any patient would prefer to take the chances of this early treatment rather than do nothing until the fully developed secondary symptoms presented themselves. Although he had no results to offer, he could abundantly testify from his own experience that the method is entirely feasible. If the mercury is employed hypodermatically in the small doses advocated in the paper no abscesses result, and there is not even thickening. The treatment, he contended, is thoroughly rational, although the investigation as to its utility is attended with many difficulties.

THE PRESIDENT spoke of the difficulties that must necessarily be encountered in such an investigation. Among these were the following: (1) The length of time before the secondary stage appears is uncertain; (2) we do not know what is the amount or kind of poison taken into the system; (3) we do not know the nature of the lymph-vessels which are to carry the virus. The disease is comparable to diphtheria. When the latter is local in character it may remain local. It remains local longer in situations where there are few lymph-vessels, as on the tonsils, and becomes constitutional at once where there are many, as about the posterior nares. The constitutional infection does not always take place to the same extent, because the lymph vessels vary in different subjects. Thus, in the fœtus and in young infants it is easy to inject these vessels, while, as the individual grows older, this becomes more difficult. But even in adults there is a great difference as regards the character of the lymphatics.

Another difficulty that presents itself is found in the fact that syphilitic infection sometimes takes place through the bloodvessels alone, as in the case referred to by Dr. Keyes. The same is true of diphtheria, and some of the very worst cases of this disease are those in which there is no glandular swelling whatever. The poison goes directly into the blood, and in these cases the discharges are apt to be more or less bloody. It is, therefore, very difficult to select the cases in an investigation like that proposed by Dr. Bronson.

A paper on *The Treatment of Flat Foot*, by Mr. Bernard Roth, F.R.C.S.E., was read by Dr. V. P. Gibney.

A resolution was then passed endorsing

THE PETITION OF THE GEORGIA STATE MEDICAL SOCIETY

to Congress to place medicines, medical and surgical apparatus, and everything used in the diagnosis and treatment of disease, on the free list.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, February 22, 1888.

THE VICE-PRESIDENT, W. W. KEEN, M.D., IN THE CHAIR.

The Vice-President, DR. W. W. KEEN, reported

A CASE OF MACEWEN'S OPERATION FOR THE RADICAL CURE OF HERNIA, FOLLOWED BY A SPEEDY RETURN OF THE HERNIA.

Macewen's operation has been so generally successful that it is the more important to report the failure of this case, as the immediate result of the operation seemed to promise a cure; but the hernia quickly reappeared.

The patient is a man thirty-two years of age, a fresco painter, but for some time at work dredging oysters. When seventeen years old he first noticed a right oblique inguinal hernia, for which he wore a truss for a year and then laid it aside. The hernia remained cured for thirteen years. A year ago, while at work dredging for oysters, the hernia returned, and descended into the upper scrotum.

He entered St. Mary's Hospital on the sixth of January, 1888, on account of the distress and inability to pursue his occupation. The operation was done on the 13th; on the fifth day I removed five of the nine external stitches, and on the twelfth day the remaining four. There was no pus at any time. The highest temperature was 100.2° F. He had then two chills, the first on the fifteenth day, his temperature rising to 103°; but as there was no evidence of suppuration, as it yielded promptly to quinine and arsenic, and as his occupation had exposed him to miasmatic infection, we were justified in attributing this to malaria.

He was kept in bed for twenty-nine days—*i. e.*, until February 11th. At this time I examined him, and found the hernia perfectly cured. He was then allowed to get up, a spica and compress being applied. Examining him yesterday (February 21), I found the hernia had returned, with, however, one gain—at the time of the operation the external ring was very large, requiring four double sutures. Now it will only admit the point of the index finger. Moreover, he is exceedingly comfortable, so much so that I doubt if I can persuade him to undergo another operation.

An incision was made over the site of the hernia to its lowest point in the scrotum. With the blunt end of the scissors and the finger, the sac was then dissected from the surrounding parts, care being taken to leave no attachment to the spermatic cord. The index finger was then passed within the abdominal wall, and the peritoneum was dissected for half an inch around the circumference of the internal ring. A moderately stout ligature of chromicized catgut was tied to the lower part of the sac, and a series of stitches taken from the lower portion of the sac to its mouth. This stitch, by means of Dr. Ellwood Wilson's curved trachelorrhaphy needle, was then passed through the abdominal wall from within outward at a point half an inch above and external to the internal ring, the skin being drawn upward and outward so as to allow the stitch to emerge through the abdominal muscular wall, but not through the skin. Then traction was made on this stitch, thus puckering up the sac, which latter was drawn through the ring and rested against the inner surface of the abdominal wall to become adherent there, closing the hernial opening by a firm pad. The stitch was then carefully secured in place. The external ring was then closed by four double stitches of chromic catgut, passed from side to side.

Dr. Keen was extremely careful in denuding the inner surface of the abdominal wall to get a large raw surface at the internal ring, so as to gain firm union at that point; and the patient was kept on his back for four weeks; yet it gave way a few days after letting him up.

DR. DULLES asked if any appliance other than the bandage was used after the patient began to go about. The hernia looked as if it had been down some time, and not as if it had descended recently. He thought it would be best not to trust solely to the strength of the tissues for a little while after these operations. There is a point in the mechanics of hernia which he has noticed, and which he has not seen described—and that is, that a patient with an inguinal hernia usually has a pendulous abdomen. He was curious to see if this spare patient of Dr. Keen's would follow the rule, and he did. He believed that the best appliance is not one which makes pressure over the ring alone, but one which corrects this abdominal outline, and changes the direction of the thrust of the intestines from one at right angles to the plane of the hernial opening to one parallel to its plane. Such an abdominal supporter as women wear would answer the purpose, and he believed that it would add to the chances of permanent success after operations for the radical cure of hernia.

DR. KEEN remarked that, of the cause of failure, he could only say that, apparently, the reparative powers did not suffice to obtain adhesion of the sac to the abdominal wall. The usual practice of those who have had a large experience with these operations has been not to use any truss. As to the exact time when the hernia reappeared he could not say. When he examined him, February 15th, four days after letting him up, it was not there. He did not see him again until February 21st, when he found that it had reappeared. He should not wait long before repeating the operation.

CINCINNATI ACADEMY OF MEDICINE.

Stated Meeting, February 6, 1888.

DR. CHRISTOPHER read a paper on

SUMMER COMPLAINT.

(See THE MEDICAL NEWS, March 3, page 229.)

DR. CLEVELAND said that it has been generally supposed that dentition plays no *rôle* in the production of summer complaint. He believed that it does exercise some influence, and that the growing teeth, pressing upon the gums, produce an irritation which reflexly has a tendency to bring about diarrhœa and other troubles. He knew that this influence was exaggerated by the laity, but he was inclined to believe that it has some foundation

in fact, and is an element that cannot be ignored. The subject of summer complaint embraces a number of conditions. Although it is termed thus, yet the disease is not necessarily confined to the summer. It occurs so frequently in summer, because the conditions which favor its development, heat and moisture necessary for decomposition, are most abundant in this season of the year. If the subject be analyzed, it will resolve itself into a question of digestion or assimilation, and that the troubles treated in books under the headings of indigestion, simple diarrhœa, gastro-enteritis, entero-colitis, summer complaint, etc., are one and the same thing, assuming different phases under different conditions. The condition of constipation ought to be considered under the same head.

A child fed on artificial foods will present certain symptoms. After it is fed for a period upon such articles it will, as a rule, grow ill. It begins to lose its plumpness, grows flabby, the secretions of the digestive tract are increased, it has diarrhœa and vomiting, is uneasy, has colicky pains, and hence cries. This continues, and a physician is called. What has caused the attack? The infant has taken starchy food, which it is not able to digest. The albuminous portion is digested in the stomach, but the remainder, passing into the duodenum, remains undigested, the pancreatic juice being insufficient to perform the task. This mass, then, acts as an irritant. It either sours, putrefaction occurs, or there takes place simply an exaggeration of the natural fecal discharges. He concurred in the treatment suggested.

Dr. Rockford thought that it would be well to bear in mind, in the discussion of this paper, what the essayist meant by "summer complaint." Under this term he embraced all the ordinary diarrhœal and catarrhal diseases, mild and severe, occurring among children during the hot months. The chief cause of these diseases the essayist believed to be some form of ptomaine poisoning, but mentioned no other manner in which bacteria may be related to them. This, then, brings us to the consideration of the question, What part do bacteria play in the causation of these diseases? Do they simply act by producing ptomaines, or are they in some other way related to the cause of them? We must remember that the bacteria of disease are few when compared with the bacteria of health, which are many, and everywhere distributed. The non-pathogenic forms are truly the bacteria of health, because they are absolutely necessary to the health and vitality of both the animal and vegetable kingdoms. The growth and development of bacteria in organic material cause the process known as fermentation and putrefaction. In this process the complex organic compounds are broken up into a great many new and simpler compounds, many of which are useful as food to the vegetable kingdom, but which by this process are rendered unwholesome and irritating to the infant stomach, even if there were no poisonous ptomaines produced by the process.

It is also a curious fact, that some bacteria in their growth produce soluble ferments, which act on starch, changing it into glucose, and on albumens, changing them into peptones. The fermentation caused by this class of bacteria is, therefore, of a very different kind from that just spoken of, in that they transform the non-assimilable starchy and albuminous food-materials into materials readily assimilated in the intestinal canal. The one process renders the food unfit for digestion, the other prepares it for assimilation. Yet the two processes are called by the same name—fermentation.

Now it is altogether probable that the bacteria which produce soluble ferments, and which, for this reason, play such a part in the digestive process at all ages, are the chief factors in infant digestion. For at this time of life the glands, which afterward take part in the digestive process, are not yet developed, and have a very feeble working capacity. With this explanation we come back to the question, What part do bacteria play in the causation of summer complaint?

1st. The disease may be caused by ptomaines, as Dr. Christopher has ably depicted.

2d. The disease may be caused by any of the many indigestible and irritating materials formed in the process of fermentation and putrefaction.

3d. The disease may be caused by anything that interferes with the growth and development of the bacteria, which are so necessary to infant digestion.

Dr. Christopher said that he had used the term summer complaint so as to avoid, as far as possible, in the name any theory as to the pathology of the affection; he had used it in preference to the name summer diarrhœa, because he had grouped certain cases of constipation under the same term.

The classification of bacteria into pathogenic and non-pathogenic is somewhat misleading, as some, at least of the so-called non-pathogenic bacteria, are capable of producing disease in man indirectly. Particularly is this true in the case of the *Clostridium butyricum*, whose action in the production of tyrotoxicon, one of the substances capable of producing summer diarrhœa, was mentioned in the paper. Fermentation is invariably the result of the growth of cells. In some of the fermentations the organisms possibly act directly, in others certainly indirectly, as when the immediate cause of the fermentation is a soluble substance secreted by the cell. In all cases of summer complaint there is, undoubtedly, some one or more of the forms of abnormal fermentation occurring in the intestine. The object of the paper was to make a general classification of these forms of intestinal fermentation, and to point out a means of recognizing them clinically, as a rational basis of proper handling of the cases. As to which of the particular products of these fermentations we are to attribute the symptoms of the disease, we cannot with absolute certainty say. But so far as we know, the only products of fermentations, generally speaking, which are capable of producing physiological effects through the nervous system, are alkaloidal substances, the so-called ptomaines. An exception might be made in the case of butyric acid, which is distinctly poisonous. It may be mentioned, in this connection, that probably all of the organic substances which are capable of producing catharsis, or the opposite condition, owe their efficacy to the alkaloids or glucosides which they contain, and which act through the nervous system. If, however, there be produced in the intestinal fermentations of summer complaints, substances other than ptomaines, which act through the nervous system in the production of the symptoms of the disease, the position taken in the paper is not affected.

As to the capability of mere local irritants, such as undigested food, to produce diarrhœa, he is somewhat sceptical. He has, it is true, recognized an acid form of

fermentation in summer complaint, and ascribed the acid fermentation to the decomposition of sugars and starches, but it does not follow necessarily, although probably, that the acid products themselves, acting as local irritants, produce the disease, and this because no starchy food, which we possess, is entirely free from albuminous constituents. Nor is this fact at variance with the clinical observation that patients suffering from this form of diarrhœa should be put on albuminous diet exclusively; because the change from a vegetable to an animal albuminoid is quite sufficient to stop any fermentation in which the former may have been concerned.

The statement made by one of the speakers to the effect that the disease may be caused by anything which interferes with the growth and development of the bacteria which are so necessary to infant digestion, can neither be affirmed nor denied, because our knowledge of the part played in ordinary digestion by bacteria in the intestinal tract is not yet sufficiently developed. It seems hardly probable, however, that the infant is left so entirely to the mercy of chance bacteria as the last-mentioned speaker seemed to imply. The cases referred to by one of the speakers as due to insolation are probably only cases of foudroyant summer complaint, the so-called true cholera infantum, and not the same disease as insolation in adults.

He concluded by saying that the classification which he had presented had been developed by the study of a large number of cases, including the careful examination of many stools. He had found it a good working rule, and could recommend it to others.

CORRESPONDENCE.

VACCINE QUILLS SHOULD NOT BE SCRAPED.

To the Editor of THE MEDICAL NEWS,

SIR: I beg the privilege of space in your esteemed journal in which to state an observation of my own derived from using vaccine virus deposited upon quills.

Last spring we had an epidemic of smallpox on this coast, and during that time there was much vaccinating done. Many of our vaccinations failed, and in quite a number of my own cases where failure ensued I observed a peculiar growth, or excrescence, spring from the point of inoculation, which, at the time, I could not explain. At first I thought it might be keloid, but it was more fungoid in character. It would usually attain the size of a large pea, become wart-like in appearance, but very vascular at the base, easily scraped off with little pain, and would then bleed very freely. These growths only came in those cases where the virus failed to "take;" and in cases where I revaccinated at the same spot, by scraping off the growth, the tumor was destroyed, and the ordinary scar was left after the vaccine ulcer healed.

This winter we have again had an outbreak of smallpox, and in vaccinating have again observed this growth follow in some cases under the same circumstances as those of last spring. I determined to solve the mystery to my satisfaction; and herewith give the secret according to my conclusions.

We have had so many failures with our vaccinations that I had been in the habit of scraping the moistened quills with a knife-blade, thinking, in that way, to obtain all the virus, and then depositing the scrapings upon the denuded surface. After observing the growths, and considering the exciting causes that were suggested to my mind, and the probability of each, it occurred to me that I had been doing "quill-grafting," in the same manner that skin-grafting is done to-day, by depositing the quill-cells upon the living tissue-cells under the most favorable circumstances to insure their growth, reproduction, and multiplication. We try to obtain the freshest virus, and no doubt many of the quills used at the vaccine farms are freshly plucked, and therefore the component cells, at the point of the quill where the virus is deposited, retain their life property of reproducing themselves under favorable circumstances for several weeks afterward.

I am positive that this is the correct solution of the matter. My partner, who used the same quills, but who was not so anxious to obtain all the virus from his quills, and therefore did not scrape them, had no like growths appear among his cases. There is no doubt that to-day there are hundreds of doctors throughout the land who practise scraping the quill when vaccinating, and I offer them the benefit of the lesson derived from my own error, and advise them to discontinue the practice. The growth is of no consequence, except the mental disturbance it is likely to cause a patient or family, who may be suspicious of any irregular occurrence following vaccination; and if scraping the quill should be much practised among physicians, it is likely to be a cause of increasing the popular prejudice against vaccination.

Very truly yours,

A. J. COMSTOCK, M.D.

SAN BUENAVENTURA, CAL., Feb. 22, 1888.

NEWS ITEMS.

The Third Annual Meeting of the Association of American Physicians will be held in Washington, D. C., on the mornings and afternoons of September 18, 19, and 20, 1888. The following preliminary programme has been issued:

The President's Inaugural Address, by William H. Draper, M.D., of New York.

Discussions on "The Relation between Trophic Lesions and Diseases of the Nervous System," will be opened by Drs. Edward C. Seguin, of New York, and William T. Councilman, of Baltimore.

And on "The Absolute and Relative Value of the Presence of Albumen and Casts, and of Renal Inadequacy, in the Diagnosis and Prognosis of Diseases of the Kidney," by Drs. Robert T. Edes, of Washington, and Edward G. Janeway, of New York.

The following papers will be read:

The Cardiac Changes in Chronic Bright's Disease, by Alfred L. Loomis, M.D., of New York.

The Relation between Chronic Interstitial Nephritis and Angina Pectoris, by Samuel C. Chew, M.D., of Baltimore.

Disturbances of the Heart-rhythm with Reference to their Causation and their Value in Diagnosis, by Gustavus Baumgarten, M.D., of St. Louis.

Fatty Heart, by Frederick Forcheimer, M.D., of Cincinnati.

The Cardiac Lesions producing the Presystolic Murmur, by Frank Donaldson, M.D., of Baltimore.

The Treatment of Valvular Affections of the Heart, by J. M. Da Costa, M.D., of Philadelphia.

Clinical Investigation in the Treatment of Cardiac Disease, by James K. Thacher, M.D., of New Haven.

Causal Therapeutics in the Infectious Diseases, by James C. Wilson, M.D., of Philadelphia.

Management of the Stage of Convalescence in Typhoid Fever, by James H. Hutchinson, M.D., of Philadelphia.

The Geographical Differences in Typhoid Fever in the United States, by W. W. Johnston, M.D., of Washington.

The Pathology of the Thymus Gland, by Abraham Jacobi, M.D., of New York.

Gastric Neurasthenia, by George M. Garland, M.D., of Boston.

Neuritis, by Francis T. Miles, M.D., of Baltimore.

The New Cæsarean Section, by William T. Lusk, M.D., of New York.

Is Hystero-epilepsy Better Treated by Medical or Surgical Means? by William M. Polk, M.D., of New York.

Demonstrations in Pathological Anatomy will be made by Drs. T. Mitchell Prudden, of New York, and William H. Welch, of Baltimore.

A National Bureau of Health.—The *Sanitary News* writes that the cheering information comes from Washington that the House Committee on Commerce will report favorably upon a bill providing for the establishment of a Bureau of Health in the Department of the Interior. This is the movement led by ex-President Sternberg, of the American Public Health Association, and if it has the support of Surgeon-General Hamilton, of the Marine-Hospital Service, is likely to become a law. It is earnestly to be hoped that all factions will unite on some measure. Everyone admits the necessity, but everyone will not give way in personal prejudice before national danger.

A Course of Lectures on Domestic Economy and Sanitation.—Domestic economy in most of our homes too often is a term wrongly applied to domestic wastefulness. A movement is on foot in connection with the extensive sanitarium at Battle Creek, Mich., which will give a correct idea of domestic economy to those who take advantage of it. The necessity for scientific instruction in many of the domestic arts, has led the authorities at the sanitarium to organize a school of domestic economy, which will be opened about the middle of March. The course of instruction will continue twenty-five weeks, and will include daily lectures, recitations, demonstration lessons, and practical drills in the following subjects: Scientific cookery, laundrying, dress-making, general housework, household hygiene, including ventilation, heating, disinfection, renovation of sick rooms, sanitary care of the house, purification of water, detection of food adulteration, etc., personal hygiene and the hygienic care of children. Keeping of accounts, and other necessary accomplishments will be taught. Certain qualifications are to be required, and a fee is charged, but arrangements can be made by which the fee can be paid in labor without interfering with the course of study. The incompetent servant girls who afflict all our large cities, and the equally as incompetent wives, would be considerably decreased by the general establishment by large institutions of a semi-public character, of such schools.—*Sanitary News.*

The Chair of Anatomy at Vienna.—The chair of Anatomy, vacant by the death of Professor v. Langer, has been offered to Professor His, of Leipsic.

Pasteur's Treatment at Barcelona.—A recent number of the *Lancet* states that the municipal authorities at Barcelona, as we announced last year, have established a municipal micro-biological laboratory, mainly with the view of enabling persons bitten by rabid animals to obtain the advantages of Pasteur's method of treatment. To the post of director of the laboratory Dr. Jaime Ferrán, whose name is well known as having proposed and carried out a system of anti-cholera inoculations, was appointed, and he has been assisted by Drs. Pauli, Commenge, and Lluch. A report of the work done from May 10 to Dec. 10, 1887, has just been published in *La Independencia Médica.* Altogether eighty-five persons have been subjected to the treatment. Of these twenty-five had been bitten by animals that were certainly rabid, fifteen by those which had been pronounced rabid by medical men or veterinary surgeons, and thirty-seven by animals which were believed to be rabid, but whose condition could not be verified by professional men. The remaining eight persons had not been bitten at all, but submitted to the process in order to prove its harmlessness. The duration of the treatment was more than three months in forty-three of the cases, more than forty days in sixty-three, and less than that in twenty-two cases. Not a single case, either of those who had been bitten or of those who had not, proved fatal. The wounds were caused by seventy-two dogs, two cats, and two mules. Two of them were not bites, but dissection wounds with instruments tainted with the virus of rabies. At first Dr. Ferrán carried out the inoculations of his rabbits according to Pasteur's method—*i. e.*, by trephining. Recently, however, he has adopted a new, and, as he believes, an improved, plan—viz., the injection of a single drop of the emulsion of the medulla containing the virus into the anterior chamber of the rabbit's eye. This produces exactly the same effects in about the same time as the trephining method.

The Limitation of the Number of Druggists in Germany.—In the *Pharmaceutical Era* for January, 1888, Pharmacist Duffield describes the system of the German Government in limitating the establishment of drug shops, and fixing the prices of licenses as follows:

From statistics we find that in very small villages in the agricultural districts, it is considered more prudential to fix the price of a new district for the first few years at about 6000 marks—$1500. For manufacturing regions, where of necessity there will be a greater daily income, the premium must be at least 8000 marks.

In towns of 3000 to 15,000 souls the price for such a district would range from 10,000 to 12,000 marks.

In cities of 50,000 inhabitants, 13,000 to 20,000 marks. For large cities the lowest price for sale of district would be 30,000 marks, and these prices rise in proportion to the size of districts, and the cities they are in—as in larger cities the profits are greater and the amount of sales very much larger than in smaller towns. Should it be determined to divide a district so as to allow another apothecary to come, the Government officer must give thorough investigation and produce authentic figures that the increase of population, etc., has been so great that

the first apothecary will not be injured in making the division. Apothecaries cannot have any other business, and especially are forbidden the sale of wine and beer (Schankgeschäft).

The "wein- und biergeschäft" is an entirely distinct business.

Two *Apotheke* under the one man's name are rarely permitted, and a *Hausapotheke* in a physician's house is not permitted unless he is five kilometres distant from the nearest apothecary shop.

In a place of 20,000 inhabitants, the exact part of the town in which the apothecary shop is to be placed is specified.

Whoever receives the grant for an apothecary district cannot sell or leave it earlier than ten years, except he becomes unfitted to do business.

There are prescribed ordinances under which an apothecary's grant can be sold or closed.

Lay Fictions About Medicine.—Under this title the *Medical Press* describes some current traditions regarding medical matters, and describes as follows a peculiar belief regarding operations upon the eye:

Perhaps the strangest fictions exist in regard to operations upon the organ of vision. Remarkable as it may seem, at least half of the number of non-professional persons who happen to be told that a friend has had an eye removed, will inquire as to the amount of sight which has been left after the operation. But even this fiction is as nothing in comparison with the almost universal one, that an eye can be taken out, carefully washed, put straight, and returned to the mutilated orbit without the slightest detriment, as part of a surgeon's day's work. One of the astounding features of these and other similar fictions is, that quite irrespective of the general enlightenment which characterizes this century, they still seem to display a vigor of existence which common sense is apparently powerless to disperse. However, as far as the medical profession is concerned, the only regret is that surgeons have not the power to take eyes out, and carry them about for a period within the refined corners of the waistcoat-pocket preparatory to transferring them at a convenient time to the tenantless orbits of various patients. It is quite possible if an operation of this nature were practicable a high premium would at once be placed upon the eyes of certain animals, and glass eyes would fall into disuse, and cease to be employed as artificial substitutes for "stopping a hole to keep the cold away."

Vaccination and Erysipelas.—A report by Dr. Airy, on three cases of so-called fatal erysipelas after vaccination, will help in forming a judgment of the sort of foundation on which the fears of an outcome of this character rest. The three children were vaccinated by three different practitioners. In the first case the erysipelas set in too late for it to be possible for vaccination to have had anything to do with causing it; in the second case the child was surrounded with erysipelas in the surgery where it was brought to be vaccinated; in the third case no definite source of erysipelatous infection could be discovered, but the child lived in a low-lying place, close to swampy and unhealthy meadows. Thus, none of these cases were traceable to the vaccine lymph; and its innocence is attested by the fact that other children were vaccinated with the same lymph without the occurrence of untoward symptoms. The question arises next as to the degree of danger of erysipelas entering the vaccination-scratch, or the wound left by a ruptured vesicle, the same as it might any other wound. According to statistics presented by Dr. Buchanan, the proportion of such accidents that occurred in England and Wales during 1883 was 51 infants dying of septic disease out of 763,192 vaccinated. —*Popular Science Monthly*, March, 1888.

The Physiology of Ventriloquism.—At a recent meeting of the Physiological Society, Berlin, Herr Meyer, from Hamburg, discussed the nature of ventriloquism, and combated the opinion, so widely spread among physiologists, that it consists in speaking while inspiring, and without the cavity of the mouth acting in any way as a resonator; on the contrary, ventriloquists speak while expiring, and do move their mouths. An extended series of laryngoscopic observations on the speaker, who has practised ventriloquism for many years, showed that in ventriloquizing the vocal opening of the larynx is shortened as it is when producing the falsetto, and that the soft palate is pressed back and that the uvula becomes invisible. Everybody who naturally possesses a high voice can easily learn to ventriloquise. One most important factor in the deception of the listeners is the contrast between the loud, full, and metallic tone in which the question is asked and the answer which immediately follows in a high and gentle falsetto. Sibilants and the high *I* should be as far as possible avoided. The speaker then gave a series of extremely successful examples of ventriloquism, which did not presuppose any particular training, and showed that it is never accompanied by any special action of the abdominal muscles. Prof. Gad has made some experiments on Herr Meyer, and by graphically recording the variations in pressure of the air, has shown that the curve obtained when a certain sentence is spoken in the ordinary way is in all respects identical with the one which is described when the same sentence is spoken ventriloquially. In the latter case the volume of air expired was considerably less than during normal speech; in one particular case it amounted to only 900 c.c., whereas during normal speech the volume expired was 1300 c.c. Dr. Benda expressed his idea that when ventriloquizing, the Eustachian tubes are open, and the cavity of the tympanum, together with the tympanic membrane, is set into simultaneous vibration. He had not been able to detect any resonance of the tympanic membrane in Herr Meyer; but he believes that this explanation of the curiously veiled tones emitted is not thereby invalidated, since they closely resemble the tones produced by speaking while yawning, in which case the Eustachian tubes are certainly open and the tympanic cavity acts as a resonator.—*Scientific American*, Feb. 18, 1888.

Sewage Farming in France.—The project to utilize the sewage of Paris in the lower part of the forest of St. Germain has been ratified by the French Chamber notwithstanding the opposition of the residents in that district, who fail to see, in the more prolific growth of cabbages and other edible vegetables, an adequate compensation for the almost inevitable inconveniences of so odoriferous a neighbor. Victor Hugo's remarks on the wastefulness of the present system of sewage disposal

in his well-known work *Les Misérables*, will not have been merely interesting if they have aided in bringing public opinion round to his views. It was urged that over £1,000,000 were lost annually to agriculture by not consigning sewage to its natural destination—the soil, but all such estimates must be taken *cum grano*, seeing that in this country, where the system has been carried out on a very large scale, and on the most scientific principles, the authorities consider themselves very fortunate if they succeed in covering their expenses—a result indeed which is very seldom attained. If the scheme prove satisfactory, and there is no reason why, with certain restrictions, it should not do so, the present system of scavenging will be abolished in Paris in favor of the principle of "everything to the sewer."—*Medical Press.*

Lime Salts in the Food and Teeth.—Miller, of Berlin, has been making experiments to determine how far changes can be produced in teeth by the presence or absence of lime salts in food. His method is to extract a tooth from a healthy dog, and then to feed the animal upon food containing but little lime salts for three months; then to remove a second tooth, and change the food to one containing an excess of salts. After four months of this treatment another tooth is extracted. The author has found that an appreciable loss of lime salts occurs in the first stage, which amounts in one case to more than one per cent., and that the proportion of lime salts rises again to normal during the second stage.—*Popular Science Monthly*, March, 1888.

Loreta's Operation on the Stomach.—Some two months ago Mr. Treves performed this operation at the London Hospital upon a man suffering from fibrous stricture of the pylorus. At the time of the operation the patient was very much reduced by pain and constant vomiting, and had been for some time unable to take food by the mouth. The abdomen and stomach were opened, and through the incision made in the viscus the pylorus was dilated with the fingers. The man made a rapid recovery, and has not vomited since the operation. He can now take any food well. The case will be shown at the next meeting of the Clinical Society.

Typhoid Infection in Sewer Air.—The *Sanitary News* of February 18, 1888, writes that a most important contribution to the study of the methods in which disease may be communicated may be looked for very soon from Professor Victor C. Vaughan, director of the Michigan Laboratory of Hygiene. Heretofore there has been lacking positive evidence as to the communication of contagious diseases through the sewer air entering the house atmosphere through defects in the house-drainage system. It has been pretty generally believed that disease could be so communicated, but positive instances of its being communicated in that manner have been unproved. The most that sanitarians have been willing to claim has been that sewer-air was improper atmosphere to breathe and might be the vehicle of germs of contagious diseases. No one has before proved that it has absolutely been known to be the vehicle by which contagious disease has been spread. This is to-day a proved fact. An epidemic of typhoid fever has been prevailing at the Michigan State Prison at Jackson. A committee from the State Board of Health was invited to make an investigation of the causes of the epidemic. The water-supply and milk-supply were first ruled out as possible vehicles by negative evidence. It was then thought that the defective condition of the sewers, combined with the insufficient supply of fresh air, was the most probable cause of the epidemic. The cases nearly all were from a distinct portion of the prison, and investigation proved that the soil pipe running from the hospital, and the house-drain into which it entered, were defective, and were pouring sewer air into that portion of the prison. Professor Vaughan took to his laboratory a sample of the air from within the soil-pipe, and has found within it the specific germ of typhoid fever. This fact explains the epidemic. The first case may have been introduced into the prison in a new prisoner, but once the germs of the disease were introduced into the soil-pipe with the undisinfected fecal discharges of the patient, the infected soil-pipe and sewer spread it freely throughout the portion of the prison into which they were pouring their contaminated atmosphere. The cause and effect are logically connected. The committee from the State Board of Health recommended that before there is any digging into the sewers or drains, there should be thorough disinfection by pouring into the drainage system, half a barrel of solution of bichloride of mercury, one part of chloride to four hundred of water; that, after such disinfection, the soil-pipe leading from the hospital be taken up and reconstructed under the direction of a competent sanitary engineer.

Nuns as Nurses in Paris.—A Paris physician, writing to the *Medical Press*, states that, contrary to the common belief, the change in the system of nursing which was inaugurated some years ago by the Paris Municipal Council was one which, with every respect to the pious and devoted sisterhood, was urgently required, and this for two sets of reasons. First of all, the nursing, as such, was far from satisfactory, as anyone who has frequented the French hospitals can testify. The work was mainly done, not by the sisters, who merely superintended, but by more or less incompetent and untrustworthy *infirmiers* and *infirmieres* who could not justly be charged with making up in zeal what they lacked in discretion.

In the second place the position occupied by the sisterhood in the hospital was based on such special privileges, rights, claims, and demands that they formed a perfect *imperium in imperio*, to the detriment of efficiency, order, and obedience. Moreover, they were incapacitated from assisting at confinements and various other categories of cases. One would have thought that our own experience of a system in which the nursing staff could beard the medical officer, and even openly decline to accede to his wishes, would have been sufficient to explain the zeal with which their services have been dispensed with. With several years' experience as an assiduous student in Parisian hospitals and elsewhere, in which the nursing was done by *religieuses*, I must confess that I cannot speak with favor of them, either as nurses or as respects their attitude toward the medical staff. I say this with some regret, seeing that personally I entertain the greatest respect both for their devotion and their abnegation.

Bread as a Disinfectant for Walls.—Esmarch concludes a series of extended experiments on the disinfection of rooms, with the conclusion that were he relying on these

experiments, to recommend a method of disinfecting walls, he should give the preference before all others to rubbing with bread. The wall is thereby most certainly cleansed from all germs; the procedure is absolutely without danger, and makes possible an immediate occupation of the room, which can scarcely be considered justifiable after disinfection with corrosive sublimate; and, finally, it is easy and inexpensive even for untrained people to carry out. He believes also that in this way the danger of subsequent infection from the wall is reduced to a minimum, so far as can be judged from the standpoint of knowledge we now possess. — *Medical Chronicle*, February, 1888.

Female Hospital Assistants in India.—The *Indian Medical Gazette* for December, 1887, states that the Government of Bengal has issued a resolution regarding the admission of female students into the Campbell Medical School for the purpose of undergoing the course of medical instruction and training laid down for Civil Hospital Assistants. It is hoped that these students will "practise in the larger villages of the mofussil under the same conditions and among the same class of the people as hospital assistants." The standard of general knowledge required before admission has been fixed at a lower level than for male students. This is a very doubtful concession to what the Director of Public Instruction calls "the want of education among women in Bengal." They are to undergo in every respect the same course of medical instruction as the male students; but special arrangements are made for their accommodation in the lecture and dissecting-rooms, for their lodging and conveyance, and ten scholarships of Rs. seven a month tenable three years have been assigned to them.

The scheme is confessedly experimental. It remains to be seen whether young native women educated in mixed classes in this and other schools will be acceptable visitors of zenanas.

Death in "Blizzards" due to Asphyxia.—MARKHAM writes to the *Journal of the American Medical Association* of February 18, 1888, stating that there is an amount of evidence and a combination of circumstances sufficient to show that the greater number of the several hundreds who lost their lives in the recent great "blizzard" of the Northwest perished from asphyxia and not by freezing. Many of the bodies, when found, were in the position of grasping or clutching at their own necks or throats. Indoor witnesses describe the atmosphere as having an appearance of density and darkness, similar to that stated by divers as existing when submerged with their armor in deep water. Many that escaped describe their peril as being from loss of breath or suffocation.

The terrific hurricane force of the wind, loaded with falling snow—the latter being by a fall of temperature, whose degree and suddenness have no recorded parallel, converted into dry crystals, and thence by the gale ground to a fine, dry ice-dust—these conditions produced a state of the atmosphere as unfit for respiration and aëration of the blood as is water for warm-blooded animal life.

Anton De Bary, a celebrated botanist and biologist of the University of Strassburg, died recently of carcinoma of the face, aged fifty-seven.

NOTES AND QUERIES.

JOSEF HOFMANN'S PULSE.

To the Editor of THE MEDICAL NEWS,

SIR: Your issue of the 25th ult. contains an able editorial on the health of the celebrated young pianist, Josef Hofmann. It may be of interest to your readers to know, in connection with the other symptoms referred to, that his temperature, taken in the mouth on the evening of the examination referred to in your editorial was a shade above 100° F., and that his pulse at the same time was 100 in the minute, and presented some irregularity in its rate, rhythm, and tension. This observation has been repeatedly made by myself, as his medical attendant before and since his examination by the medical commission from whose report the above facts are gathered. Very respectfully,

SIMON BARUCH, M.D.

NEW YORK, March 1, 1888

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM FEBRUARY 28 TO MARCH 5, 1888.

FISHER, W. W., *First Lieutenant and Assistant Surgeon.*—Sick leave extended one month on surgeon's certificate of disability.—*S. O. 50, A. G. O.*, March 2, 1888.

SHILLOCK, PAUL, *First Lieutenant and Assistant Surgeon.*—(Recently appointed.) Ordered for duty at Fort Assiniboine, Montana.—*S. O. 50, A. G. O.*, March 2, 1888.

APPOINTMENT.

SHILLOCK, PAUL.—To be Assistant Surgeon, with the rank of First Lieutenant, January 31, 1888.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MARCH 3, 1888.

HEYL, T. C., *Surgeon.*—Orders to the Receiving Ship "St. Louis" revoked.

WHITE, C. H., *Surgeon.*—Present duty continued to October 1, 1888

STREETS, T. H., *Surgeon.*—Ordered to the Receiving Ship "St. Louis"

DRENNAN, M. C., *Surgeon.*—Ordered to the Receiving Ship "Vermont."

BRUSH, G. R., *Surgeon.*—Detached from the Receiving Ship "Vermont," and ordered to the "Pensacola."

MEANS, VICTOR C. B., *Past Assistant Surgeon.*—Detached from the Naval Hospital, New York, and ordered to the "Pensacola."

HOCHLING, A. A., *Medical Inspector.*—Detached from the "Pensacola," and wait orders.

HARMON, G. E. H., *Passed Assistant Surgeon.*—Detached from the "Pensacola," and wait orders.

EDGAR, J. M., *Passed Assistant Surgeon.*—Detached from the "Pensacola," and waiting orders.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING MARCH 3, 1888.

STONER, G. W., *Surgeon.*—Detailed as Chairman of the Board for the Physical Examination of Officers and Candidates, Revenue Marine Service, February 28, 1888.

URQUHART, F. M., *Passed Assistant Surgeon.*—Detailed as Recorder of the Board for the Physical Examination of Officers and Candidates, Revenue Marine Service, February 28, 1888

KALLOCH, P. C., *Passed Assistant Surgeon.*—Relieved from duty at Pittsburg, Pa.; ordered to Marine Hospital, San Francisco, Cal., March 2, 1888.

CARRINGTON, P. M., *Passed Assistant Surgeon.*—Relieved from duty at Marine Hospital, San Francisco, Cal.; ordered to assume charge of service at Pittsburg, Pa., March 2, 1888.

KINYOUN, J. J., *Assistant Surgeon.*—Granted leave of absence for twenty days, February 28, 1888.

ORIGINAL ARTICLES.

NOTES ON PROGRESSIVE STUDIES IN ETIOLOGY, AND ESPECIALLY AS TO MICROÖRGANISMS AS SOLE FACTORS OF DISEASE.

BY EZRA M. HUNT, M.D.,
SECRETARY OF THE NEW JERSEY STATE BOARD OF HEALTH, TRENTON, N. J.

FOR the past few years no subject has more attracted the attention of physicians and sanitarians than the relations of microörganisms to disease. So soon as medical experience and some approach toward science began to take the place of superstition it could not but be that inquisitive minds would seek to know the cause of disease. This was especially the case with epidemics that seemed to light on persons and places regardless of choice. It was at once natural and plausible to maintain that the visitation was independent of locality. The wind bloweth where it listeth. It is "the epidemic constitution of the atmosphere" was the learned phrase under which ignorance of causation was concealed. So in 1839 we hear Dr. Farr, the Registrar-General of England, saying:

"Difficulties in the history of plagues and contagious diseases of every description have generally been disposed of summarily by the hypothesis that the disease is always introduced from without and spreads naturally—like a conflagration. It is true that they are frequently introduced thus, but this neither proves that all diseases are always thus introduced, nor does it at all show the relation of the number of cases of seizure or of mortality to the conditions of persons and surroundings."

It was not long before the awakening medical mind began to suspect that it was necessary to guess about or explain what this impalpable vapor, particle, or thing might be which *introduced* the pestilence. Fortunately, many conceived that there were other practical questions also, such as, How to limit extension and mortality after arrival? But there were some early inquiries in the direction of seeking the relation of certain living particles to disease. About fifty years ago, Dr. Holland, in his *Medical Notes and Reflections*, discussed the hypothesis of infusoria as at that time a more probable doctrine than that of vegetable parasites. In the *British and Foreign Medical Review* for April, 1840, is to be found the following:

"The hypothesis that the causes of epidemics are generations of minute insects transmitted from one individual to another through the medium of the atmosphere, has been ingeniously put by Dr. Holland, in his *Medical Notes and Reflections*. Henle, of Berlin, has supported the theory by new facts and analogies. The diffusion of contagion has a close analogy with fermentation; and Cagniard-Latour and Schwann have shown that fermentation is the decomposition of organic fluids by minute vegetables of the lowest class. Putrefaction is a destruction of organic matter effected by infusoria, and not a mere decomposition into elements. One contagious disease, the muscardine of the silk-worm, is known to depend on the development of a vegetable parasite. The germs are innumerable, and spread with the greatest rapidity. In mixtures, certain genera of infusoria appear, and then give place to new genera. Individual cases of disease may be caused by one generation of parasites; an epidemic by successive generations. Each epidemic disease has its specific animal contagion, its specific genera of infusoria. Henle has proved the existence of this cause, and the theory in every way but one; he has never seen the epidemic infusoria. The omission is, no doubt, important; and the more so on the part of Henle, who is justly considered one of the best microscopic observers in Germany. The infusorial hypothesis does not satisfactorily explain the cause of epidemics; it accounts for them by the creation of animalcules, but does not show why the animalcules are created at distant times in swarms. The phenomena of swarms of insects, of blight, and of infusorial generation may suggest investigation, but in the present state of pathology they cannot supply its place."

Earlier than this, in 1833, Dr. Tyler had enunciated the fungoid doctrine of disease as accounting for the origin of the cholera in India. This pamphlet of sixty pages was entitled "Facts Establishing the Deleterious Properties of Rice as an Article of Food," see *Lancet*, vol. I. 1833–4. In 1838, Boehm, of Berlin, had written his article "Die kranke Schleimhaut in der Asiatischen Cholera, Berlin, 1838." As to it in 1866 Sir John Simon said:

"If the doctrine of a cholera-fungus should hereafter be substantiated, it will probably be conceded that Boehm deserves the credit of having first published a thoroughly valid account of the phenomena of cryptogamic vegetation in choleraic intestines and discharges, and Hallier's researches do not better join on to the recent essays of Thomé and Klob, than they might have joined, in 1838, on to those of Boehm. The fifth section of his admirable little book is entitled 'Ueber das Vorkommen der Garhungskeime (Pilze) im Nahrungs-kanal der Cholerakranken." In it he describes as almost constant, that the whole extent of the intestine (but generally the large intestine the least) teems with a vegetation of microfungi; that innumerable round and oval, or more elongated, corpuscles are to be found in all the vomit and dejections as well as in the canal; sometimes single, sometimes two, three, four, or more joined end to end, as links of a chain; and these chainlets sometimes branching; that such forms are held together in mucous floccules and come best to light when liquor potassæ is used; that within the small intestine they are often so numerous that not the smallest specimen will fail to show numbers of roundish, fungic forms amid the débris of epithelium. He appends an illustration which shows quite

unquestionably the forms of cryptogamic growth, and refers, for similar forms, to Schwann's then recently published investigations of yeast."

Henle too, in 1840, in his *Pathologischen Untersuchungen* showed that the "contagium vivum" that had been indefinitely talked about must be a living organism, since it grew and multiplied in the body of the infected host by assimilating other substances than its own. Even by the light of modern microscopic knowledge we cannot wonder at the imperfect distinction between these low forms of animal and vegetable life, although we now owe so much to plant-pathology in the elucidation and confirmation of the subjects. It was really this vitalistic view of contagion that Pasteur revived about 1860.

In 1848, "Dr. Cowdell, of Dorchester, England, sought to establish on theoretical grounds that cholera must depend on a microscopical fungus absorbed through the lungs into the blood and multiplying in the blood and bowel."

Early in 1849, Prof. Mitchell, of Philadelphia, had published his article "On the Cryptogamous Origin of Malarious and Epidemic Fevers."

In the autumn of 1849, there was, says Dr. Simon, for a few weeks a great deal of talk in England about the cholera-fungus. This arose from the publication of Drs. Brittan and Swayne, of Bristol, in the *Medical Gazette* and *Lancet:*

"These writers had for some two or three months been acting in relation to cholera as a microscopical committee for the Bristol Medico-Chirurgical Society, and in their examination of choleraic discharges had, independently of one another, observed, often in very large numbers, certain peculiar forms ('annular bodies,' 'cholera cells,' etc.) which they believed to form a connected series, and to be characteristic and causative of the disease. These forms, they said, were of smaller size in the vomit than in the dejections; and Dr. Brittan, stating that he had found still smaller bodies of the same sort in the atmosphere of cholera districts, put forward a note from Mr. John Quekett, then an eminent microscopist, to the effect that he having examined Mr. Brittan's specimens from air, vomit, and dejection, 'had no hesitation in stating that in his judgment they were successive stages of development of the same body, which he believed to be of a fungoid nature.' Dr. Budd, of Bristol (*Times*, September 26th), added that he had found the same peculiar microscopic objects 'which seem to be of the fungus tribe in great numbers in almost every specimen of drinking water which he was enabled to obtain from cholera districts;' a statement which appeared particularly important in connection with the very original and remarkable views then recently put forth by the late Dr. John Snow, in a little paper which now has historical interest, 'On the Mode of Communication of Cholera;' for Dr. Snow was contending that cholera is primarily an affection of the intestinal canal; that it is excited by the accidental swallowing of contagious matter discharged from the bowels of the sick, something which being swallowed can increase and multiply within the stomach and bowels; and that the great agent of such infection is drinking water. Dr. Budd in the above quoted letter, and in a pamphlet which he soon afterward published to the same effect, brought the various views interestingly together, and recommended as a most important precaution the disinfection of the discharges of the sick by receiving them 'into some chemical fluid known to be fatal to the fungous tribe."

But the adverse report of a committee of the College of Physicians and the cessation of the cholera seemed so to suspend this view that only Dr. Swayne answered the committee.

It was not until about 1866 that observations in the same general direction, made by Thomé, Klob, and Hallier turned new attention to the subject. These are thus described by Dr. Buchanan in his abstract of Professor Ernst Hallier's recent researches into the natural history of the cholera fungus (1866).

"Hallier's observations were made on the stools of a person with cholera at Berlin in 1866, and on the stools and vomit of a cholera patient at Eberfield in 1867. In the stool from Berlin, the characteristic vegetable elements consisted of a fine fungiform matter (Hefe) which floated, and of more highly developed spore-cysts (Fruchte) which sank to the bottom. These spore-cysts are described as yellow or brownish bodies, consisting of a pale membrane inclosing highly refracting, colored spores. The cyst-wall undergoes a series of changes, ending in its rupture or solution, and the spores then become free. The spores, by progressive partition—a process which may begin before they leave the cyst—resolve into very small cells, grouped into balls and heaps which Hallier calls "colonies" of micrococcus. The small cells of micrococcus constitute the fungiform matter (Hefe) which is the other vegetable element seen in the evacuations. The minute micrococcus cells attach themselves to any bodies there may be in the stool—to remnants of animal or vegetable food, to epithelium cells, or to oil globules; and under the influence of the micrococcus, these and all nitrogenous matters got a dirty aspect and lost their structure."

The chief advance of Hallier seems to have been in the detection of "highly developed cyst-formations with the contained spores in a state of actual germination." No one can go over his researches and experimental methods without recognizing how far he approached toward investigations that have since been accounted as original. Indeed, it is to such botanists as Hallier, Hoffmann, Cohn, and Davaine that we owe the revival of interest in the study of these minute forms, some of which it is believed had been seen by Leuwenhœcke as early as 1675, and since by various observers, but had not been so closely associated with diseases. But now the attention of physicians had been arrested, as had been that of Prof. Panum (1856), of Copenhagen, and a few others. From 1870 onward the relation of microörganisms to disease has been as prominent among pathological as among botanical investigators. "The researches of MM. Davaine, Hallier, and Cohn upon the bacterium of charbon and the micrococci of contagious maladies were taken up by chemists, pathologists, and microscopists, until in 1876, the papers of Cohn and the skilful cultivations of Koch of the bacillus anthracis so as to carry it through the stages of development and give its life history, established, in one instance at least, a direct relation between a microörganism and a disease. But

physicians generalize much more rapidly than do most painstaking specialists in so minute inquiries. Although ten or more years have passed, we may well remember that it was Cohn who says:

"So long as the makers of microscopes do not place at our disposal much higher powers, and as far as possible without immersion, we will find ourselves in the domain of the bacteria, in the situation of a traveller who wanders in an unknown country at the hour of twilight, when the light of day no longer suffices to enable him to distinguish objects, and when he is conscious that, notwithstanding all his precautions, he is liable to lose his way."

With this caution, at that time, we have good reason to inquire as to our progress since.

It will, we believe, show that most laborious and valuable work has been done, and that we are in the region of great possibilities in the effort of restraining or preventing disease. But it will also show us that too many of the *practitioners of medicine* are generalizing and arriving at conclusions faster than the biological investigators.

First of all, let it be noted that since then (1880) Magnin closes his treatise thus:

"As to their *rôle* (microörganisms) in fermentations, in putrefactions, in contagious diseases and in surgical lesions, notwithstanding the considerable number of labors of which the bacteria have been the object in the different points of view, it is not yet possible to define it in a certain manner."

Surgeon Sternberg, the translator, adds his own approving and emphasizing note.

In 1886 E. Klein opens his excellent manual on microörganisms and disease by cautioning us against taking "as proved what has really not passed beyond the stage of possibility."

Following Prof. Koch, he then states the conditions, without which, "in no instance, can it be said to have been satisfactorily proved; that a particular infectious disease is due to a particular microörganism." He then enumerates five non-pathogenic or septic organisms, and sixteen pathogenic forms, as claimed to have been subjected to some or all of the tests proposed.

Of these, the only ones with which the practitioner among human diseases has in general to deal are: typhoid fever, malaria, anthrax, tuberculosis, and Asiatic cholera. It is notable that neither smallpox, measles, scarlet fever, diphtheria, nor whooping-cough is included. It is also noticeable that as to the microörganisms of typhoid fever, Klebs, Eberth, and Koch are not in agreement that they have not answered the crucial tests relied upon by bacteriologists, so that Klein does not regard them as shown to be "necessarily or intimately connected with typhoid fever."

As to malaria, the observations of Tomassi-Crudeli have not been accepted as conclusive by any considerable number of bacteriologists, while the malarial germ of Laveran has claims to recognition.

As to the tubercle bacilli, the presence of this special form, among others, in tuberculosis is admitted, but so long as such observers as Toussaint, Klebs, and Schüller claim that tuberculosis is due to a microörganism, which is a micrococcus and not a bacillus, and so long as Schottelius and Klein deny the identity or interchangeability of the human and the animal (bovine) disease, although the same microörganism is found, we certainly cannot assert it to be proven that this is the *causa vera* of the disease.

Opposite the comma-bacillus of Asiatic cholera there are still several interrogation points. "Comma bacilli of various species have been found in other diseases of the alimentary canal; in the fluid of the mouth of normal persons (Lewes), and in old cheese (Denike)." Similar criticisms apply to most of the microphytes claimed as the cause of some animal diseases, and even certain variations as to anthrax, are still dubious. Thus Pasteur, p. 154, says they do not form spores; at p. 426 Klein says they do.

Prof. A. De Bary, in the recent edition of his *Lectures on Bacteria* (Oct. 1887) states similar views with great precision, and with many cautions against too rapid scientific or clinical deductions.

Says Prof. De Chaumont (1887), "Those who have followed the development of the (microbe) question during late years know what extraordinary studies have been made and yet we are, as it were, merely hovering about the gate and have barely entered the field at all. Some who have got within the gate astonish us with their accounts, more or less confused, of the wonders to be found within, while others still stand outside on the beaten track crying out that there is nothing in the field and that all is vanity."

Also, "It is true that we have the bacillus of anthrax and the bacillus of tuberculosis, the connection of which with these diseases is undoubted, but it still remains to be *proved* that each is 'teterrina causa morbi.'"

As "It is shown that pathogenic bacteria (or what are believed to be so) propagate best under unhygienic conditions, light, fresh air, and pure water being inimical," it behoves us to give great consideration to *that class of causes which are generally most decisive of results.*

Such facts as these do not show but that we are in a wide and important field of investigation, since the presence of special and typical forms may be a great aid to diagnosis, and the cessation of the forms under treatment may point to the best therapeutics; but we must not assert that these *cause* the disease until more evidence is in, and a little more analysis and summing up occurs. So Dr. Karg, of Dresden, in his recent summary of the work of Weisser well remarks, "One must admit that our knowledge of the conditions of life for the micro-parasites, notwithstanding the most zealous labors in the field of medicine, are by no means so advanced that we can give a satisfactory and comprehensive judgment concerning their action in the living organism in which the relations are so exceedingly complicated."

There are now other considerations that must be given due weight.

(*a*) All animals do not show the same results, and it is unsafe, therefore, to infer that culture experiments in animals verify what would or does take place in man. Thus, "Rodents, carnivorous animals, and monkeys must be considered unsusceptible to cholera. In connection with all the experiments said to have yielded positive results on guinea-pigs, it must be mentioned that a variety of bacteria are known, which, although derived from *normal* but putrid secretions, act very poisonously on rodents—*e. g.*, the bacillus isolated by Bienstock from normal human fecal matter; the dumb-bell micrococcus isolated by Pasteur and Sternberg from normal saliva, by Escherich from the stool of milk-fed infants, and by Klein from sputum in pneumonia" (see Klein, p. 186).

(*b*) On the point of the harmful effects of septic bacteria in diseases regarded as specific, read, for instance, the abstract of the report of Prof. E. Crookshank to the Agricultural Department of Privy Council, read before the London Pathological Society, January 17, 1888, and to be found in the *Lancet* of January 21, 1888. Thus he identifies the streptococcus pyogenes of acute abscesses as present in various diseases. He says, "For some time my attention has been drawn to the probable identity of organisms described in puerperal fever, measles, scarlatina, and diphtheria with the chain-forming micrococcus in pus, and I find that, independently, bacteriologists on the continent have not only considerably extended that idea, but have come to definite conclusions." He names over twenty diseases of the communicable class in which the presence has been noted and recognized as the determining factor as to gravity of attack. "Thus, Passet, Biondi, Eiselsberg, Baumgarten, and Fränkel have definitely accepted the identity of the streptococcus associated with suppuration, and the streptococcus associated with erysipelas. The same has been asserted by good authorities as to hospital gangrene and puerperal fever (see Rosenbach, Fränkel, Cushing, and Baumgarten). So as to diphtheria, Fehleisen and Baumgarten found the species identical with the streptococcus in erysipelas. It is admitted that there are differences of manifestation, but the same essence. Similar results were asserted by skilled and accepted observers as to scarlet fever and other diseases. This accords with the clinical observations of Sir William Jenner long since made as to the agency of sepsis in the determination of grave symptoms and fatal results in scarlet fever and diphtheria."

(*c*) There is still respectable disagreement among leading authorities as to whether common or septic may change into pathogenic microörganisms, or as to possible modifications of pathogenic forms by culture and surroundings, as also of their products. Klein, for instance, while taking ground against Buchner and Sattler as to harmless microörganisms assuming pathogenic properties under the influence of soil or surroundings, still speaks of it as an "open question." Compare Billroth, Nägeli, Zopf, etc., who still more open the question as to the effect of modifications of species and of their effects due to the poison or environment.

(*d*) It is only of late years that we have come to recognize the very great numbers of different classes, species, and groups of microörganisms that are often present, and at different times present or absent in the same disease or in the same fluids, and so the task of differentiating which are hurtful and which is the one and the only one that is operative constantly; which is pathognomonic of the disease, and its specific cause is rendered more difficult.

(*e*) It is one thing to find a form or class always present, and another thing to prove that it is the *fount and origin*—the *true cause* of the disease. Cheyne, speaking of the tubercle bacilli, says, "It is probable that a variety of conditions, such as special predisposition, are necessary before they can grow in the living body." This applied to various diseases, simply indicates the meaning that a diseased or abnormal condition being in the system, the appearance of microbes of special forms belongs to the phenomena of disease, or is one among the causal relations.

Presence in itself considered never indicates cause, but often an effort of nature to deal with and dispose of disease products. De Bary says a microbe may be diagnostic of disease, and yet not be its cause.

(*f*) It was only after much had been said of the microörganisms of disease that we came to realize that the *rôle* played in the economy of nature, or of animal life by microörganisms is *essential* for the maintenance of life. Hence it was almost a surprise when we reached the term *harmless bacteria*, and still more the term *indispensable bacteria*, and finally have so good an authority as Watson Cheyne sum up an article on the subject (1884) by proposing an inquiry as to how to so deal with the pathogenic organisms as to make them useful instead of hurtful.

(*g*) Microbes have so much to do with what are after all chemical processes that we are not to so far accept biology as to overlook chemical metabolisms of disease. The biological facts still leave a study of disease from the standpoints of physiological and pathological chemistry. Germane to this is the recent paper of M. Vignal to the Académie des Sciences, published in *La France Médicale*, No. 99, an article in which not only are the number and variety of microbes in the alimentary canal noted, but the remarkable or different powers of chemical metabolism which they exercise. The claims of Pasteur for the wonder-workings of microbes in the usual processes of digestion, and their necessity, are in the same line.

(*h*) A new field of inquiry opens as we study the

products of microörganisms and the poisonous products of decomposition. As to either of these we do not yet know all the relations that are biological or all that are chemical. Thus, in anthrax it is not the bacillus, but, as Hoffa and others have shown, "the poison products accumulating in the blood that cause the fatal issue." So there is claimed to be a cholera ptomaine. See, also, the researches of Brieger on the tetanus bacilli, and of Rosenbach as to the two alkaloids, tetanin and tetanotoxin, both of which, introduced into animals (without the bacillus) produce their specific action. So in the various ptomaines (Selmi) and leucomaines we have to deal, perhaps, with chemical products, and not with actual animal or vegetable life *in situ*. In fact, septic poison or sepsin results from various chemical processes which in themselves are destructive of every living microörganism.

(*i*) More recently we have important contributions as to the coöperations and antagonisms of different classes of microörganisms, showing that the destruction of one form may be the removal of the most hopeful method of getting rid of another form.

Dr. Garre, a leading Swiss bacteriologist and lecturer at Basle University, has recently studied the relations existing between a non-pathogenic bacterium growing in putrescent fluids, in the water of wells, etc., and shown its antagonism to the bacillus typhosus, etc. "The explanation of the antagonism lies in the fact that microbes secrete some specific, highly diffusible substances which prove poisonous to certain species of bacteria, while having no effect on others." He shows, by several experiments, that it is not the crowding out or starving out of one species by another, but a direct germicidal effect (see *Fleming's Veterinary Journal*, October, 1887, p. 305).

This brief review is of itself sufficient to show that we are very far from being prepared as yet to settle the relations of microörganisms to each other, or to disease; to define which are specific and which are not, to tell how pathogenic organisms become so, or how they produce results; whether they are causative or merely coöperative; in a word, are not prepared to base any system of clinical practice thereupon.

This caution is not so much needed by the bacteriologists, many of whom give full weight to such facts, as by those who from some special results or discussions point to special and positive conclusions. The study of what is actually present in disease is always important, not only as finding whether the presence is an *arrival* which has initiated the processes which constitute the disease, but also as finding what are its other exact relations to the disease. For, if finding either that it is integral or incidental to the disease, or only diagnostic, in either case it is important to know the effect of this action on the sickness. It is essential that the practitioner shall always bear in mind "that the pathogenic effect depends upon several conditions, such as the source of the microörganism, the dose, the mode and place of infection, and the nature of the inoculated soil." Our only design is thus to draw attention to the actual status of microphytic knowledge, so far as it concerns practical hygiene or practical treatment of disease, so that we may not too early assume as a basis what is not yet proven. This, at the same time, stimulates us to such constant inquiry as may be indicated, and as is hopeful for the future of both of these important sciences and arts.

OSTEOPLASTIC RESECTION OF THE FOOT (WLADIMIROFF-MIKULICZ).

By STEPHEN SMITH, M.D.,
of New York.

Two cases of the new operation of osteoplastic resection of the foot, as devised and practised by the surgeons mentioned in the title of this paper, have been reported in this country.[1] I am able to add another case, and as the operation seems to be one of great promise, I desire to add my own to the list, chiefly because of its failure:

The patient was aged twenty-one, of apparently good health. In November, 1885, he received a severe crushing injury to the heel of the right foot in a railway accident. The process of repair was very slow, and finally terminated in considerable retraction of the heel, but without a complete closure of the wound. He first came under observation April 13, 1886, when the foot presented the following appearance. The heel was drawn up and firmly flexed, the wound was but partially healed, and in his efforts to walk the wound rapidly enlarged, and he was compelled to take to his bed. He was urgent to have his leg amputated. As amputation, or resection, offered the only chance of securing a useful extremity, resection was proposed, and the osteoplastic operation of Mikulicz explained to him. He much preferred amputation, as that was the only operation which had been suggested to him by physicians whom he had consulted. He finally consented, though reluctantly, to resection, and it was accordingly performed on May 14, 1886.

The precise steps of the operation were nearly those detailed by Mikulicz in his paper.[2] Fig. 1, taken from his publication, will best illustrate the several stages of the procedure. Esmarch's elastic bandage was employed and antiseptic pre-

1 The Osteoplastic Resection of the Foot, as devised by Wladimiroff and Mikulicz. By Christian Fenger, M.D., Journal American Medical Association, January 29, 1887. Report of a case of Wladimiroff and Mikulicz Osteoplastic Resection of the Foot. By William Barton Hopkins, M.D., THE MEDICAL NEWS, December 3, 1887.

2 Archiv. für Klinische Chirurgie, 1881, Bd. 26, Heft 2, p. 494.

cautions taken. The patient was placed in the abdominal or prone position; an incision was commenced (*a*) just in front of the tuberosity of the scaphoid on the inner border of the foot, and carried down to the bone across the sole of the foot to a point behind the tuberosity of the fifth metatarsal bone (*b*); from the ends of this cut two incisions were carried upward and backward to the base of each malleolus; the ends of these incisions were

FIG. 1.

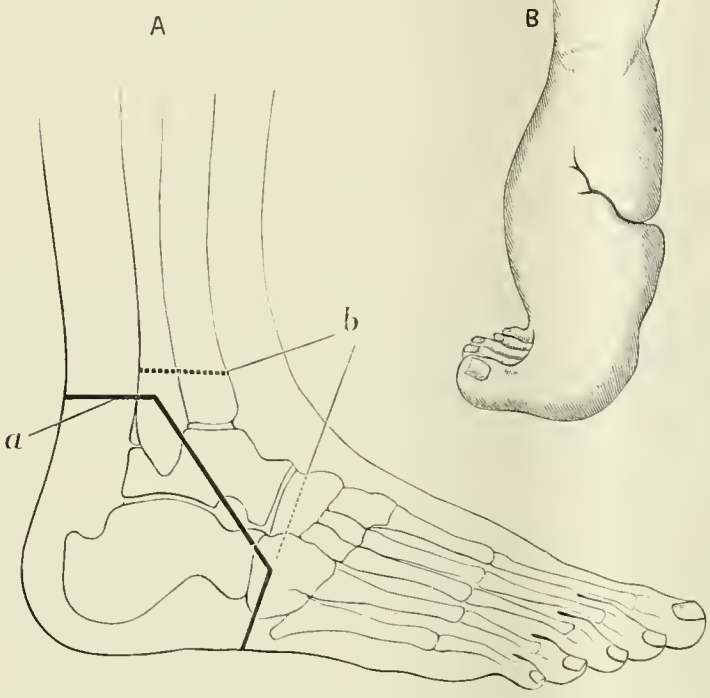

FIG. 2.

next united by an incision across the posterior surface of the leg (*a*) at that point; the foot was then carried in dorsal flexion and enucleation effected at the ankle-joint from behind forward, the astragalus and os calcis being dissected away from the soft parts in front. The malleoli and the articular surfaces of the tibia and fibula were next sawn off and then the articular surfaces of the scaphoid and cuboid bones were removed (*b*); the foot was then placed in a straight line with the leg, and the resected tarsal bones assumed a very easy and natural apposition to the divided ends of the tibia and fibula. Two silver wire sutures were inserted into the apposed bones, one at the external and the other at the internal angle. All of the opposing deeper structures of the wound were then united by catgut sutures; the divided tendo-Achillis being attached to fibrous tissues of the sole, and the cut tendons of other muscles united accurately. Two small drainage tubes were inserted, the usual antiseptic dressings applied, and the limb was finally fixed in proper position by the gypsum bandage.

The wound progressed admirably while he was under my care, there being no fever or suppuration. A slight slough of the old cicatrix occurred about a suture. It was very noticeable, however, that the patient was dissatisfied with the peculiar foot that he had, and this discontent was aggravated by his companions who visited him and ridiculed his appearance. He became very morbid and began to urge amputation through the leg. He was encouraged to await results, but in vain. Finally, when out of the hospital on leave he disappeared, and did not return for upward of eighteen months. He had meantime, had his leg amputated and returned to have the stump amputated. He has since succeeded in having his limb amputated twice.

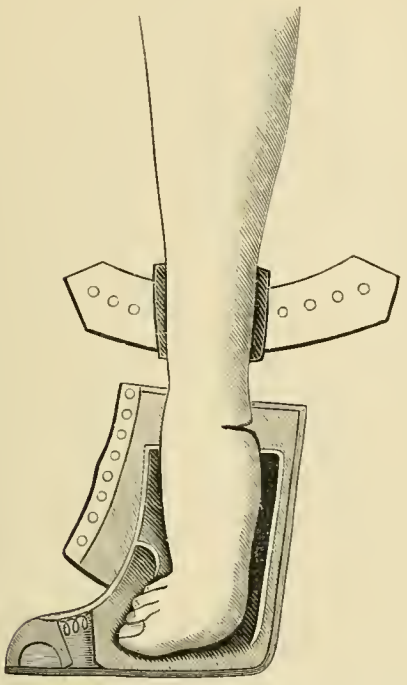
The failure of the operation was, therefore, due to the conduct of the patient rather than to the conditions of the wound.

As this patient passed from under my care before the completion of the cure, I did not have an opportunity to perfect the position of the toes. This has proved to be an important procedure. It will be seen (Fig. 2, B) that the toes are to be fixed in a position of extreme extension, or dorsal flexion. To effect this object Mikulicz divided the contracted tendons and forced the toes into the position indicated, and maintained them in this state by apparatus. Fenger states that after the wounds were healed in his case "The toes of the foot were fixed in semiflexion, and as they possessed but little mobility it became necessary to effect their complete dorsal flexion in order to enable the patient to walk on the balls of the first phalanges, . . . the patient was again anæsthetized and the toes were forcibly extended, *i. e.*, flexed on the dorsum of the foot. The flexor tendons, as well as the metatarso-phalangeal joints, had (from non-use) almost entirely lost their mobility; the skin covering the plantar surfaces of the joints was contracted. As a consequence of this condition the skin gave way beneath the first and second metatarso-phalangeal joints, and the first phalanx of the great toe was fractured just anterior to the joint." The toes were maintained in this position by a plaster cast. The wounds healed in about a month, and he was supplied with a boot designed by Mikulicz (Fig. 3). Subsequently the cicatrix on the plantar surface of the great toe opened, and was finally closed by a plastic operation.

Dr. Hopkins has so fully discussed the several questions relating to the operation, in a recent number of THE MEDICAL NEWS, that it remains for me only to express my strong convictions of its value, and the importance of familiarizing the surgeons of

this country with its details. It is true that it is applicable to but a limited number of cases, but in

Fig. 3.



those cases it is to be preferred to any other method. It is very easy of execution, very successful as regards the cure, and affords a most useful limb for progression.

574 Madison Avenue, New York.

A CASE OF ABDOMINAL SECTION.

A Contribution to the Subject of Exploratory Laparotomy.

By WILLIAM M. MASTIN, M.D.,
of Mobile, Ala.,
Fellow of the American Surgical Association, etc.

Laparotomy as a diagnostic measure, although receiving the unqualified advocacy of a few bold operators, has not attained a place among established surgical principles, but, on the contrary, remains a doubtful and unsettled procedure.

Such a position is, to say the least, surprising in this day of heroic surgery, where no part, it matters not how vital, of the complex human organism is beyond the reach of the knife; and especially when it is remembered that the operation of opening the abdominal cavity, its contents subjected to rude manipulation, and often extensive mutilation, is of daily, if not hourly, occurrence, and with formulated rules, definite and explicit, ready for our guidance in the necessities for and technique of its performance. But the fact is, that examples of exploratory abdominal section bear a very small ratio to the immense number of what, in contradistinction, may be designated as operative laparotomies, and to this paucity of clinical records may be ascribed measurably its condition of uncertainty.

The present status of abdominal surgery certainly demands more extended and exact knowledge concerning this important subject, and for its proper estimate it becomes essential that a careful and comprehensive analysis be made of numerous cases of *strictly* exploratory operations—that is, where the abdominal incision is not followed by additional surgical interference. Hence the report of clinical records is, of course, indispensable, since from this source alone can be secured the deductions requisite for determining the value and limit of its applicability; and, therefore, I offer this case as a small part of the needed mass of evidence.

It is true that operative laparotomy has solved already some of the questions which arise in this inquiry, but still it is necessary to examine the entire subject anew that we may ascertain just how far laparotomy can be employed in the diagnosis of obscure abdominal lesions, and chiefly, 1, the character and extent of danger in the operation *per se;* 2, to what class of cases it is applicable; 3, the necessity for large and small incisions, respectively, and their relative gravity; 4, the influence exerted over existing non-operable lesions of the contained viscera; 5, what effect may be anticipated upon coexistent diseases, both systemic and of distant regions.

The subjoined case, besides presenting many interesting features, furnishes very material aid in answering several of these queries; at least, in this instance, it demonstrates that the operation in itself is devoid of danger, although the abdomen was opened to the extent of seven inches, and the tumor cut into; that it afforded perfect command of the situation—permitting an accurate determination of the character, extent, and relations of the growth—which could have been gained by no other method; that, although the subject of grave pulmonary disease, this was not aggravated; but, on the other hand, the general condition of the patient was markedly improved; that the tumor itself was, apparently, beneficially influenced by the procedure, diminishing several inches in all directions, and remaining so five months after operation, when the last examination was made.

Case. *Large, solid, abdominal tumor (splenic); pulmonary tuberculosis; exploratory laparotomy; adhesions dense and extensive, with such vascularity as to prevent removal; improvement in systemic condition; diminution in size of growth; prompt recovery from operation.*—Lucy W., mulatto, æt. thirty-six, domestic; married, 7-para; medium stature, but frail, slender, and not strong. Family history good as far as known. She has always enjoyed moderate health, with no severe sickness except occasional malarial outbreaks, and two or three attacks of hæmoptysis within the past year. She considers herself well at present, although she is somewhat

enervated, has a little cough, and complains of loss of appetite.

About two years ago she consulted me relative to a movable lump in the left side, with the dimensions of a cocoanut, and which then had been noticed for a year or longer. It was painless, and only gave annoyance from its size and location. Examination showed it to be of the above description, occupying the left hypochondriac and lumbar regions, adherent apparently to the anterior abdominal wall for an area of two inches, and presenting the shape, consistency, and other characteristics of a hypertrophied spleen. In addition, miliary tuberculosis of the left lung was diagnosed. She was also several months advanced in pregnancy. Quinine, arsenic, etc., were prescribed, and she was advised to return at intervals.

She was not seen again until July 21, 1887, when she returned on account of the rapid enlargement of the tumor, which was double its former size. The late pregnancy seemed to have given an impetus to its development. The growth was slightly tender, and, at times, quite painful, which, together with its dragging weight and size, produced extreme discomfort. It extended from beneath the ribs on the left side vertically downward within the boundary of the left inguinal region, and transversely beyond the middle of the epigastric and umbilical spaces. More fixed in its position, and the area of attachment to the abdominal wall had extended with its increased dimensions. It had very much the feel and contour previously noted, with the exception of a prominent anterior lobe (the portion adherent to the abdomen), below which was a cleft in the lower edge, which appeared to correspond to the notch frequently met with in the spleen. Manipulation and pressure did not cause pain. The uterus was free and movable. She had lost flesh considerably, was weak and anæmic, and there was some increase in her cough, and a little expectoration. She was nursing her infant of thirteen months. Physical examination showed increase in pulmonary trouble, there being subclavicular dulness on both sides, especially the left, with prolonged, jerky, and harsh breath-sounds, lessened expansion, with depression. She had had a moderately large hemorrhage several days since. A rough estimate revealed a slight increase in white blood-cells. I advised weaning the child; ordered cod-liver oil, iron, etc., and suggested that an exploratory operation should be performed a few weeks later, and the removal of the tumor, if found practicable.

Sept. 12. General condition improved; size of growth increased, especially in the transverse direction. Its vertical length measured eleven inches; transverse length was thirteen and a quarter inches; and the circumference of the body around the most salient part of the growth equalled thirty-one and a half inches. Abdominal raphé displaced to the right. Numerous large veins course over the abdomen. Umbilicus pouting.

21st. Admitted to the Providence Infirmary, and placed on preparatory treatment.

26th, 1.30 P.M. Operation under ether. Strict antiseptic precautions, without the spray. A median incision, which it was necessary to lengthen to seven inches, disclosed a firm, solid, capsulated growth, so densely adherent on all sides as to be inseparabl blended with the attached structures, and exceedingly vascular, with large vessels distinctly visible beneath the capsule. The adhesion with the anterior abdominal wall was dissected loose to the extent of about one inch, in which the capsule was necessarily torn and the tumor superficially cut into, but the hemorrhage was so excessive as to render removal of the growth much beyond the limit of safety. For the control of the bleeding eight suture-ligatures of gut were required. Cavity washed out with a 1 : 8000 sublimate solution to remove blood, wound united with continuous catgut suture (peritoneum separately, then muscles, fascia, and skin), line of incision painted over with iodoform collodion, pads of sublimated gauze and cotton adjusted, over which was placed a wide flannel bandage. The operation, including dressing, lasted one hour, one-third of this time being employed in arresting hemorrhage. No shock, and reaction prompt. Six hours after operation the patient was resting nicely, without pain or uneasiness, with pulse 100 and temperature 99°. The subsequent progress of the case was uneventful, except, on the twelfth day, an attack of surgical mania of a night's duration. The highest temperature reached was 101°, pulse 130 and feeble, on the evening of the second day (September 27th), but under quinine in full doses, combined with digitalis, it gradually declined and fell to the normal on the eighth day. Liquid food (milk) was allowed on the second day, prior to which time water alone was given. Bowels moved by enema on sixth day.

Oct. 6 (eleventh day). Examined wound, which is dry and firmly united, the sutures coming away attached to the collodion pellicle, thus healing under a single dressing.

Patient up and walking about on the fourteenth day, and discharged on October 11th, two days later.

To the eye the abdomen appears decidedly reduced, which is confirmed by measurements, showing circumference of body around tumor to be twenty-eight inches; vertical diameter nine and a quarter inches; and transverse diameter ten inches.

Notwithstanding the confinement, etc., she has gained flesh, and professes to feel better than for a year.

Feb. 20, 1888. Reëxamination indicated no increase in growth—the dimensions remaining unchanged—and her general health is still improved. She is able to do light work, and experiences no inconvenience or discomfort from the tumor.

FRACTURE OF THE LARYNX.

By M. HOWARD FUSSELL, M.D.,
of Manayunk, Pennsylvania.

A case of this rare injury came to my notice on July 9, 1887, under the following circumstances:

The patient, Edward E., æt. fifteen years, a catcher of a local baseball nine, was engaged in a game of ball with some of his fellows on a half holiday. He

was in his position behind the bat, two men were on bases, he wore his mask and stood close behind the batter. A ball was pitched and the batter made what is technically called a "foul tip"—that is, the ball was struck by the bat, but in such a position that it was driven backward with great velocity instead of forward.

The patient, as is stated, wore a mask, but just before the ball reached him, he threw his chin upward and the ball struck him squarely in front of the neck. He did not immediately fall, but threw off his mask and placed his hands to his neck. In a very short time he spat up considerable pure blood, and breathing began to become difficult. He walked several hundred yards and spoke several times, but at the end of half an hour he became unconscious and remained so until after tracheotomy was performed.

I saw him one hour after the accident. At that time he was unconscious, his face and hands deeply cyanosed, and bloody froth exuded from his mouth. His breathing was stridulous, much like that of a child in the last stages of membranous croup. On examining the front of the neck it was found flattened and considerable emphysema on both sides of the neck. On the least manipulation of the larynx fearful paroxysms of suffocation would come on, and crepitation between the alæ of the thyroid cartilage was plainly felt.

With the kind assistance of Drs. Griffith and Trites, of this place, tracheotomy was performed. The patient made such violent struggles on the trachea being touched that it was absolutely necessary to administer an anæsthetic. A very small amount of ether was administered carefully by Dr. Trites. As rapidly as possible a cut was made down to the trachea, the veins were much engorged and great care had to be exercised in order to prevent laceration of the swollen vessels. In a few minutes the trachea was reached. Just before I was able to open the trachea respiration ceased completely. I hooked up the trachea with a tenaculum, made an incision through three rings and slipped in the tracheotomy tube. Still the boy did not breathe. His heart was beating, though feebly. I immediately performed artificial respiration after the Silvester method. A large amount of bloody froth issued from the tracheotomy tube. After several artificial movements of the chest wall, the patient took one long inspiration and again stopped. Artificial movements were again performed, and finally, after an almost inconceivable amount of bloody froth was pumped out, the boy breathed regularly and his heart-beat rapidly became stronger.

After he had been breathing for about fifteen minutes, the tube, which was short, slipped from the trachea. It was immediately replaced only to slip again after a few minutes. It was again replaced, but before replacing it a stitch was taken through the edge of the trachea. The tube was then replaced and the thread connecting with the trachea tied around the shoulder of the tube. This was necessary because the tube was a short one, and the only one in the place. If the trachea was not drawn up toward the tube it continually slipped. From that time on the patient breathed more and more naturally. In half an hour he opened his eyes and answered questions by nodding his head.

The trachea was opened about 5 P.M. At 8 P.M. the patient was doing excellently. I retired from the room for about fifteen minutes. When I returned I found a deepening cyanosis, the tube was in place and bloody froth was again exuded with each act of respiration. The lungs were again becoming congested. The pulse was 90, full and strong. I turned to get my hypodermatic syringe; before I reached the table respiration stopped abruptly. I quickly felt for the pulse but it was absent. No action of the heart could be heard or felt.

By an unfortunate combination of circumstances a post mortem was not secured. As stated above, however, crepitation between the alæ of the thyroid was plainly felt. When I removed the tube after death I examined the trachea as carefully as possible and found it almost entirely occluded above the incision. The occlusion was apparently due to the thyroid being pushed backward. The tube was in place and free from obstruction.

So far as I am able to discover, this is the seventieth recorded case of fracture of the larynx and the fifty-fourth death.

The case is unique in its cause and in the mode of death.

When the peculiar risk to a ball-catcher is taken into consideration it seems strange that such an accident should not have occurred before.

The recorded deaths, which have occurred suddenly, have all been before tracheotomy, and generally due to increasing dyspnœa from œdema. Atlee reports a case where death occurred suddenly from general emphysema.

In my case the breathing was normal just previous to death, save a slight congestion of the lungs due to the remains of the first severe congestion. The ingress and egress of air were not impeded.

The character of the pulse less than a minute before death being so excellent, and the sudden stoppage of the heart would suggest as the cause of death a sudden pressure on the pneumogastrics in the neck.

In the absence of a post mortem it is, of course, impossible to state the condition of the surroundings of these nerves, but the swelling of the neck progressively increased from the time the patient was first seen.

It is scarcely probable that administration of the ether (which was necessary owing to the struggles of the patient and the lack of intelligent assistants) could have had any part in causing the fatal result, three hours having elapsed between the administration and death. There was no organic disease of the heart shown by physical examination.

189 Green Lane, Manayunk.

TREATMENT OF CHRONIC BRONCHITIS IN CHILDREN.

BY THOMAS J. MAYS, M.D.,
PROFESSOR OF DISEASES OF THE CHEST IN THE PHILADELPHIA POLYCLINIC.

A GOOD deal is said in our text-books on the treatment of acute bronchitis in the child and in the adult, but there are cases constantly occurring in the practice of every physician which do not fall under the description of the acute form of this disease, and which pursue rather a chronic or subacute course. A child from two to ten years old, and even younger, is brought before you, who has had a cough for some time, which is accompanied by yellow expectoration in the morning but is of a lighter color during the day. The child is able to be about, but its respirations are accelerated, and are short and shallow; the pulse is quickened; there is occasionally a flush in the face, probably a slight rise in temperature; night sweats; loss of flesh; dyspnœa; poor appetite; coated tongue; and the presence of general debility. On inquiry you will find that some months previously this child contracted "a cold," or had an attack of measles, or whooping-cough, from which it made an imperfect recovery and consequently has not felt well since.

Palpation of the chest probably reveals a fremitus over the central portion of the chest, both anteriorly and posteriorly; there is no dulness, but rather increased percussion resonance, and a roughened, blowing respiration is heard over the whole chest which may be accompanied by rhonchi, mucous and sibilant râles, audible especially in the morning after rising. Coughing will remove the râles, but not the blowing breathing.

Quite an extended experience in the treatment of these cases teaches us that persistent counter-irritation is of the first consideration. If there is much impediment to the ingress and egress of air, or, in other words, if there is much dyspnœa, the child is at once placed in bed, the chest is enveloped with a hot flaxseed meal poultice (covered well with oiled muslin) which must be changed every three hours. In most cases, however, it is not necessary to order the child to bed, and counter-irritation is produced with a mild croton oil liniment. Croton oil and sweet oil, well mixed in the proportion of one to two parts of the former to six of the latter, is well rubbed into the skin of the child's chest—in front, under the arms, and between the shoulder-blades, not with a flannel or cloth, but with the mother's or nurse's fingers, twice a day, and then the chest is well covered with a layer of cotton-wool. It is important that as much as ten or fifteen minutes be spent in rubbing the liniment well into the skin, after which the hands must be thoroughly washed. In the course of four or five hours a red blush of the skin will appear, ending in fine, yellow-pointed pustules. Simultaneous with this eruption the cough becomes easier, the expectoration more free, the dyspnœa less—in fact the most remarkable change will be brought about in the little patient.

Our attention was first called to the usefulness of this application by Dr. Park in a short contribution to the London *Practitioner* for March, 1882 (p. 170), and although he principally recommends it in acute bronchitis, we can say that we have found it as useful in the form of bronchitis here described as he did in the acute form of the disease. Indeed, we may add that we have also given it a fair trial in acute catarrhal affections of the chest in children and never had any reason to feel disappointed with its action.

The internal treatment must be directed toward a stimulation of the bronchial mucous membrane, and toward a recovery of the appetite. The former will be attained in a great measure by the following combination:

R.—Ammoniæ murias. . . . ℥j.
Ex. euphorbia pil. fld.,
Tinct. digitalis . . . . āā fl. ℥iij.
Atropiæ sulph. . . . . gr. $\frac{1}{70}$.
Chloroformi . . . . gtt. xij.
Syr. tolu,
Syr. picis liquid. . . . āā q. s. fl. ℥j.
Aquæ . . . ad. q. s. fl. ℥iv. M.
Sig. One teaspoonful every three hours.

For the purpose of aiding digestion, and as a general tonic the following will be found useful:

R.—Acid. phosphorici (dil.),
Acid. nitromuriatic. (dil.),
Acid. sulphuric. aromat.,
Tinct. ferri chloridi . . āā fl. ℥ss. M.
Sig. Thirty drops in sweetened water after each meal three times a day.

The diet should be exceedingly liberal, although no food must be allowed which is likely to disagree. Our main reliance must be placed on rich milk, soup, oatmeal, beef, mutton and other kinds of nutritious food. At no time during the treatment is it necessary to confine the child within doors during pleasant weather. Indeed, out-door exercises should be encouraged as much as possible.

MEDICAL PROGRESS.

Oil of Gaultheria and Salol in Rheumatism.—DERCUM reports his experience in the use of these drugs as follows in the *Journal of Nervous and Mental Diseases* for January, 1888:

Regarding the dose of oil of gaultheria, I have been in the habit of prescribing ten or twenty minims of the oil to be taken at intervals of three or four hours. This has, on the average, proved sufficient to produce marked impression within twenty-four or forty-eight hours, as evidenced by the subsidence of pain and ringing in the ears.

Occasionally I have given it in larger doses and at shorter intervals. In one instance, a case of muscular rheumatism in which the pain was obdurate and excruciating, I gave a half drachm every two hours, with the result of a rapid, absolute, and permanent relief. In this patient, five or six doses of the drug were taken before marked symptoms of gastric disturbance became evident. The fifth or sixth dose—I do not remember exactly which—was rejected by the stomach. The patient's pulse became rapid, the tongue coated, and his nausea was extreme, and to judge by the description given by himself, "cinchonism" was excessive. He described the ringing in the ears as frightful. However, he reacted quickly, and although he had been sickened by the oil he was cured of his pain. On the following day, in fear that his pain might return, he of his own accord resumed the drug in smaller doses.

Under circumstances in which the patient ceases to be tolerant of the drug, it has been my habit of late to fall back on salol.

In my own experience, salol has special virtues of special application. It is an almost tasteless, fatty, insoluble powder, which is as bland and unirritating to the mucous membrane of the stomach as so much powdered paraffine would be. It is apparently not acted upon by the gastric juice, but depends for its digestion upon the pancreas. At least it is decomposed in the small intestine into salicylic and carbolic acids. This change likewise takes place when salol is mixed with pancreatic secretion or with pancreatic tissue outside of the body.

As far then as the stomach is concerned, it is innocuous and inert, and it frequently proves a grateful relief to that viscus, especially when the oil of gaultheria or the salicylate of sodium has been given for some time. Judging from my own experience, it is slower in producing its physiological action than the other salicylates. The effect is not as pronounced and much less prompt. That it is, however, efficient in the same class of cases as the oil of gaultheria there can be no doubt. I generally prescribe fifteen or twenty grains to be taken every three or four hours. The effect is gradually produced, and is manifested in large doses by more or less "cinchonism." Curiously enough, I have noticed that the ringing in the ears is less, but the deafness more marked, than from the gaultheria. Occasionally patients will mention the darkening of the urine due to the presence of carbolic acid.

Now and then patients object to the drug on account of its greasy feel and greasy taste, and sometimes of their own accord ask to be placed back on the gaultheria. Occasionally, of course, it is well to alternate the gaultheria, instead of with salol, with the sodium salicylate.

Further Testimony to the Value of Creasote for Phthisis.—Von Brunn, in the *Berliner klinische Wochenschrift* of February 20, 1888, reports that in the past eight years he has treated 1700 cases of pulmonary phthisis with creasote, with good results. His cases were not only the ambulatory patients in whom there was no marked rise of temperature, but also cases in which tuberculosis was making active progress. The best results were obtained in acute cases in which the temperature became nearly stationary after a period of fever, and in which the lesion was generally catarrhal and unilateral. Regarding dosage, von Brunn considers it an error to give less than six or seven minims of creasote daily; he has not exceeded seven minims daily, and considers it essential to continue this treatment for at least several months. He believes with Sommerbrodt that the more creasote which can be borne the better. The creasote wine originally prescribed by Bouchard was found to be the best form for administration:

Creasote	13 parts.
Tr. gentian.	30 parts.
Spts. vini rect.	250 parts.
Vin. Tokaya, or Malaga	ad. 1000 parts.—M.

Sig.—Teaspoonful well diluted with water three times daily.

Tuberculous Laryngitis Cured by Lactic Acid and Iodoform.—Luc reports, in *L'Union Médicale* of February 16, 1888, the case of a young woman who was the subject of pulmonary tuberculosis, and in addition tuberculosis of the larynx. After anæsthetizing the larynx with a solution of cocaine, 1 to 5, he destroyed the granulations most prominent with the electric cautery. The subsequent treatment was the application of lactic acid fifty per cent., and powdered iodoform. The laryngeal lesions healed; the pulmonary condition was uninfluenced.

Iron in Purpura.—A chemical examination of the blood, bile, pleuritic effusion, brain, liver, spleen, marrow of the bones, kidney, lungs, and lymphatic glands in a case of purpura has been made by Dr. Zaleski, and published in the *Russian Military Medical Gazette*, his object being to determine whether this disease, which is called by him "morbus maculosus Werlhofii," is associated with any increase in the quantity of iron in the body, as some results obtained by Hindenlang and Kunkel appear to indicate. Dr. Zaleski found that, so far from this being the case, the iron was diminished by something like a half. He found no inorganic iron compounds like those described by Kunkel, but most of it existed in the form of an albuminate; some, however, was found in the pigment spots in very stable compounds similar to hæmoglobin. More iron appeared to exist in the gray than in the white substance of the brain.—*Lancet*, Feb. 18, 1888.

Formulæ for the Use of Hydrate of Amylen.—Fischer is quoted by *L'Abeille Médicale* of February 20, 1888, as using the following formulæ:

Amylen hydrat.	grs. 100.
Aquæ destill.	ʒ 3½.
Ext. glycyrrhizæ	ʒ 2½.

Half to be taken on retiring.

With morphia:

Amylen hydrat.	grs. 90.
Morph. hydrochlor.	gr. ¼.
Aquæ destillat.	ʒ 15.
Ext. glycyrrhizæ	ʒ 2½.

Half to be taken on retiring.

Per rectum:

Amylen hydrat.	grs. 75.
Aquæ destill.	ʒ 12½.
Mucilag. gummi Arab.	ʒ 5.

And with morphia:

Amylen hydrat.	grs. 60.
Morphiæ hydrochlorat.	gr. ¼.
Aquæ destillat.	ʒ 12½.
Mucilag. gummi Arab.	ʒ 5.

Antiseptic Midwifery in the Boston Lying-in Hospital.—In a recent discussion upon the subject of antiseptic midwifery, Dr. William L. Richardson, in closing the discussion, said he had been fourteen years at the head of the Boston Lying-in Hospital, where septicæmia had been so prevalent that they had repeatedly been compelled to close the hospital. Since the introduction and adoption of the antiseptic method in 1885, they have had over nine hundred confinements, without a death from septicæmia. With regard to diagnosis, he thinks peritonitis a comparatively rare complication of septicæmia, but regards a temperature of more than 100° F. as evidence of it. Milk fever, swelled legs, mammary abscess, sore nipples, pneumonia, are all evidences of it. Under the antiseptic method, women pass through the puerperal period without any rise of temperature whatever, and torn perineums unite by first intention without the slightest difficulty.

He considers the physician responsible if a death occur from any of the above enumerated causes. In his opinion, the question is bound to assume a medico-legal aspect, and it will go hard with a physician who loses a patient from any such cause, unless he can succeed in shifting the responsibility on the nurse. With regard to technique, it makes no difference whether pads or towels are used, or whether the pads are used wet or dry. Garrigues uses them wet, but in Boston they are used dry, because the wet pad, if long continued, may cause eczema, and, possibly, mercurial poisoning. He has abandoned the post-partum douche, except in cases where it is positively indicated,

There is little danger of absorption from the endometrium, but much more danger that the mercurial will be absorbed in the folds and small rents so constantly present in the vagina. Digital examinations may be practised *ad libitum* previous to delivery, provided the examining finger be washed in the mercurial before introduction.—*Boston Medical and Surgical Journal*, March 1, 1888.

An Ice-bag over the Spleen in Typhoid Fever.—Weichardt has employed an ice-bag wrapped in flannel, laid over the spleen in typhoid fever, and thinks that a reduction of temperature and a hindrance in the development of bacilli resulted.—*Präger medicinische Wochenschrift*, January 11, 1888.

A Sugar Test.—Mr. Marson recommends sulphate of iron and caustic potash as a test for the presence of sugar in urine. One and a half grains of the pure salt are dissolved in about 120 minims of urine by the aid of warmth, then five grains of caustic potash added and boiled. If sugar be present, a dark green precipitate will form, the superjacent liquid being reddish-brown or black, according to the amount of sugar. If no sugar be present, the precipitate is greenish-brown in color, and the liquid is colorless.—*Medical Press*, February 15, 1888.

Aseptic Leaden Bullets.—Rolland, by experiments upon animals, has found that, so far as the eye is concerned, it is neither the form nor the chemical composition of the grains of lead, but the asepticity that accounts for their not producing panophthalmitis after penetrating the vitreous. This asepticity is due to their disinfection by the deflagration of the gunpowder.

Secondly, when leaden pellets are not sterilized immediately before entering the eye they produce panophthalmitis with the same frequency as other metallic bodies. If copper, iron, or brass fragments are similarly sterilized by gunpowder, they are as harmless as lead shot in producing panophthalmitis.—*Medical Chronicle*, Feb. 1888.

Formulæ for the Treatment of Chronic Coryza.—Mackenzie prescribes a nasal douche containing the following powder dissolved in half a glass of warm water:

Sodii bicarbon.,	
Sodii biborat.,	
Sodii chlorat.	āā grs. 6.
Sacchar. alb.	grs. 15.

The temperature of the solution should be 98.6° F. The fluid may be snuffed up the nostrils, or injected by a small syringe.

Moure prescribes an antiseptic douche of

Acid. carbol.	parts 20.
Glycerin.	parts 100.
Alcohol	parts 50.
Aquæ	parts 350.

Of which a teaspoonful or dessertspoonful should be added to a pint of warm water.—*L'Abeille Médicale*, February 20, 1888.

Spontaneous Rupture of the Rectum.—Dr. Quénu, in his clinical lesson at the Beaujon Hospital, treated of spontaneous rupture of the rectum, and related in detail the following case, which is not wanting in interest. A woman, æt. sixty, of a very weak constitution, had suffered for the last six years from a prolapsus of the rectum, which, however, she reduced with facility. Being habitually constipated, she made a free use of purgatives, and frequently passed blood. For the last six weeks she seemed to suffer more than usual, and kept her bed. The day of the accident she made great efforts in defecation, and suddenly she felt something come down, and great pain followed, with a considerable loss of blood. A doctor who was called in ordered her to be sent to the hospital, and when M. Quénu arrived he found the woman pale and cold, and on raising the chemise a portion of the intestine a yard in length was discovered black and shrivelled. Introducing the finger into the rectum, a large rent by which the intestine escaped was felt in the anterior wall. Under chloroform, the abdominal wall was incised in the median line, and nothing but blood was discovered. The herniated intestine was removed close to the anus, but all attempts to suture the rent were useless. Iodoform dressing completed the operation. The patient succumbed on the following day. The autopsy revealed a rent of an inch and a half in length, and a considerable amount of varicose veins, which M. Quénu considered pathogenic.—*Medical Press*, February 8, 1888.

The Toxic Principles of Snake Venoms.—Vincent Richards writes, in the *Indian Medical Gazette* for December, 1887, in support of the conclusions reached by Weir Mitchell and Reichert, that the active principles of snake venoms are proteids, and not alkaloids. He cites the conclusions of Norris-Wolfenden and Gibbs on this point, which agree fully with those of Mitchell. Wishing to secure, if possible, a consensus of opinion from those

who have studied the subject, he addressed a communication to Gautier, enclosed a specimen of cobra venom, and asked him to report his studies in the light of recent investigations. The conclusions which Gautier has reported from his latest experiments are at variance with those of all other authorities, and Richards considers them based upon the examination of too small a quantity of venom.

Richards, in agreement with Mitchell and others mentioned, considers that the action of alkalies and of heat upon serpent venom confirms the view that these poisons are not alkaloids, but proteids.

Nitro-glycerine in Epilepsy.—Osler, in the *Journal of Nervous and Mental Diseases* for January, 1888, reports his use of nitro-glycerine for epilepsy, as follows:

I have notes of nineteen cases in which the nitro-glycerine was tried for periods ranging from six weeks to six months. In thirteen of these cases there were severe epileptic seizures, six were instances of *petit mal* with occasional convulsions. Briefly stated, in nine cases there was improvement, as shown in the reduction of the frequency of the attacks. Of these, six were cases of major epilepsy; and three, instances of petit mal. The benefit was usually manifested within a week or ten days. Thus case 16, a man aged twenty-seven, had had fits for ten years; and when seen, April 5th, had as many as two or three a day. He had taken potassium bromide largely, and at one time with great benefit. Antifebrin was given in gr. viij, two or three times a day, but seemed to be without any influence. On June 1st, nitro-glycerine was given, ♏v of the one per cent. solution, three times a day. Within a week the attacks were greatly lessened, and in the second week after beginning he had only two attacks. He continued to take it all through the summer, getting up to ♏viij doses, t. i. d. He does not think that anything he has ever taken reduced the fits so much. On November 11th, he stated that he had stopped it for a month; the attacks have recurred less frequently, and he had been able to be at work.

In some of the cases in which the betterment was most striking at first, the remedy seemed to lose its influence, and after a month or two had to be abandoned. I cannot say that in any one of the nine cases the improvement has been more than temporary. In two of the cases of petit mal the attacks were greatly reduced, and one patient remained free for two months, but I learn by letter that the attacks have returned. Altogether my experience has not been very encouraging. We may say that, in a limited number of cases, when the bromides have failed or are beginning to lose efficacy, nitro-glycerine may be used with advantage. I have also used the nitrite of sodium in a few cases with indifferent success.

Albuminuria and Renal Lesions Following the Injection of Albumen.—Snyers, in *L'Union Médicale* of February 14, 1888, reports the results of the injection of albumen in animals as follows:

The albuminuric dyscrasia caused by injections of white of egg, ceases in twenty-four hours after injection; white of egg being useless as such in the organism is eliminated by the kidneys without producing a lesion of those organs. After thirty days' continued injections histological examination fails to reveal lesions of the kidneys, from which it is concluded that injection of albumen fails to produce even physiological albuminuria.

Salicylic Collodion.—Bivert, an apothecary of St. Petersburg, finds the following a successful formula for preparing salicylic collodion:

R.—Collodii	. . . . .	parts 100.
Acid. salicylic. crystall.	. .	parts 10.
Terebinth. venet.	. . .	part 1.
Chlorophyli	. . . .	q. s.

This collodion is especially useful as a remedy for corns.—*London Recorder*, Jan. 20, 1888.

Death by Suffocation in Phlegmonous Tonsillitis.—Dr. Way reports, in the *Medical Record* of February 25, 1888, a case in which he had incised the tonsils for phlegmonous inflammation, with temporary relief.

On the following morning I visited him, and found the tonsils swollen about as badly as on the previous afternoon, prior to my incising them. He reported himself as having been able to sleep some during the night, though not so well as he should have liked. His temperature was 102.6° F.; pulse 96; and general condition as good as usual in similar attacks. I applied iodo-tannin to the inflamed glands, and also an emollient poultice to the neck over the situation of the tonsils. The quinia and gargles were also continued, and the patient was advised to remain in bed. At 10.30 P.M., I visited him again, and found him in about the same condition as in the morning. His pulse was 94; temperature 102°; he had been able to take some fluid nourishment during the day, and said he believed he would be able to get out on the morrow, if he could only get some sleep.

His throat presented much the same appearance as in the morning. I again administered the hypodermatic of morphia (gr. $\frac{1}{8}$) and atropia ($\frac{1}{120}$), as on the previous evening, and a few minutes later retired to a room on the same floor of the building, two doors removed from the patient. An hour and a quarter later I was hastily summoned to attend my patient by a gentleman who was occupying the same apartment with him. His tone betokened alarm, and without dressing, or waiting to question him, I hurriedly repaired to his room. My patient was dead! Intravenous and intracardiac injections of ammonia, with artificial respiration practised more than half an hour, failed to elicit at any time the slightest evidences of vitality. Examination of the body of the deceased revealed the fact that the upper pharyngeal region and the larynx, especially the latter, contained a large quantity of pus and broken-down tonsillar tissue, derived from the rupture of the right tonsil. There were no evidences of cardiac or renal disease; *per contra*, the deceased had always, saving the frequent attacks of tonsillitis, enjoyed excellent health.

From his companion I learned that within fifteen or twenty minutes subsequent to my departure he had sunk into a peaceful slumber, breathing quietly and without any difficulty for almost an hour. He then seemed to stop breathing for a moment, but soon made one or two ineffectual gasps for breath, which so alarmed his companion that he rushed out of the room and down the hall to my room. In not more than one minute from the first respiratory difficulty I was at the bedside, but the life-principle was then entirely extinct.

Theine in Pain.—In the *Journal of Nervous and Mental Diseases* for January, 1888, MAYS reports the following formula for the use of theine in pain in various regions of the body:

R.—Theinæ,
Sodæ benzoat. . . . āā ʒj.
Sodæ chloridi . . . . gr. viij.
Aquæ . . . . . f ʒj.—M.

Sig.—For hypodermatic use. Six minims equal one-half a grain of theine.

Administered to a properly adapted case, theine is surprisingly prompt in its analgesic action. He has on numerous occasions observed patients with lumbago, who were too stiff to bend their bodies, or had almost too much pain in their back to rise from a chair or sit down after they were up, comfortably straighten their bodies in less than five minutes after its introduction. When not so prompt, it is probably due to the small size of the dose, and where one-half of a grain does not produce the desired results, it should be increased to one, or even two grains.

When injected, it gives rise at first to some burning, but it does not produce any prolonged irritation or inflammation. The burning is soon replaced by an area of anæsthesia.

The Treatment of Lead Colic by Rectal Injections of Ether.—TORRE, in the *Bulletin Général de Thérapeutique* of February 15, 1888, reports that he has given ether per rectum for the spasms of lead colic with good results. He employed a flask containing about a drachm and a half of ether, to which was attached a rubber tube of convenient length and terminated by the canula of an irrigator. The injection of fifteen to twenty minims of ether was often sufficient to mitigate a severe spasm when enemata of castor oil and soapsuds were given to relieve constipation.

A Positive Test of Death.—MASCHKA has advanced the theory that a burn upon the surface of a cadaver is not followed by the formation of blebs, as upon the living body. He advises the actual cautery as an infallible test in cases of suspected death.—*Präger medicinische Wochenschrift*, January 18, 1888.

A Tonic Pill, for Use in Phthisis.—In the *Therapeutic Gazette* of February 15, 1888, BRUEN gives the following formula:

R.—Iodoformi . . . . . gr. ½.
Acid. arseniosi . . . . gr. $\frac{1}{10}$ to $\frac{1}{60}$.
Pil. ferri carb. . . . . gr. j.
Ext. cannabis ind. . . . gr. $\frac{1}{5}$.
Quiniæ sulph. . . . . gr. j.—M.

Diet in "Large White Kidney."—The *Medical Press*, of February 15, 1888 writes that the condition known as the "large white kidney," a malady of tolerably common occurrence, is due in a large number of cases to the chronic irritation set up in the eliminatory organs by the excretion of incompletely oxidized nitrogenous matter resulting either from excess of nitrogenous material ingested or from hepatic or other visceral disease. In either case it is important to bear in mind that the object to have in view is to reduce, or at any rate not to augment, the quantity of these partially oxidized products. For this reason albuminuric patients should avoid foods containing an abundance of these extractives. Beef tea, beef extracts, and the like are little less than poison to them, as they infallibly accentuate the irritation and aggravate its results. It has been found that the systematic subcutaneous injection of these substances in guinea-pigs gave rise to the characteristic renal lesions with the usual train of symptoms, the severity of which was in direct proportion with the quantities injected.

The Treatment of Follicular Enteritis.—WIDERHOFFER, in addition to a strict limitation of diet in these cases, employs enemata of mucilaginous fluids containing small quantities of opium. A child of six months would receive an injection of twelve and a half drachms of fluid, with one drop of tinct. opii.

Intestinal lavage is usually performed with about one quart of a solution of salicylic acid, 3 to 1000, which is considered preferable to carbolic acid. A solution of chlorate of potassium is also useful. In the more advanced stages of the disease astringents—alum, rhatany, or tannin—may be employed. Guarana, in doses of three-quarters to three grains in five or six daily doses, may be given by the mouth as follows:

Guaranæ pulv. . . . . gr. ¾ to 3.
Sacchr. pulv. . . . . q. s.

Tannate of quinia, in doses of three-quarters to two and a half grains, has been used with excellent results. Widerhoffer urges great caution in convalescence, as prolonged digestive troubles follow these patients.—*Revue Gén. de Clin. et de Thér.*, February 16, 1888.

Fatal Somnambulism.—The *Boston Medical and Surgical Journal* of February 23, 1888, reports that on the night of the 15th inst., a gentleman aged sixty-eight years, residing at Oak Knoll, Danvers, Mass., left his bed while asleep, and walked forth from his house clad only in his night-shirt. He was found the next morning frozen to death, about a quarter of a mile from his house. The thermometer marked from eight to ten degrees below zero that night. The same man, who had been afflicted with somnambulism for some years, is said to have nearly perished in a similar way once before. He went from his house one cold night, but was observed and brought back, having, however, to suffer the amputation of a finger that was frozen.

Chloride of Methyl in Neuralgia.—DR. ABRAHAM JACOBI has used chloride of methyl in five cases of trigeminal neuralgia; two were old cases, three recent ones. In one case there was relief and cure after the first application. In the two old cases relief followed two applications. One case was that of hyperæsthesia along the whole course of the trigeminal; the first application gave relief, and at a recent date a letter from the patient states that there has been no return of the trouble. In a case of neuralgia with pain extending through from breast to scapula, instantaneous relief was obtained, but the pain recurred; in this patient every remedy had been fruitlessly tried, except morphine; the latter alone had afforded relief.

As to pigmentation of the part sprayed by the methyl,

Dr. Jacobi has had only one case that can be called serious: the discoloration seems, in this instance, to be permanent, but he does not regard this feature as a sufficient objection to forbid the use of the remedy. He further says, "I can imagine nothing more easily manipulated and of more instantaneous action than the methyl spray. It has not the continuous pumping of the other sprays." He had not been able to carry his experiments as far as he desired for the reason that his supply of the methyl had been limited.

The abstract given above has been taken from the discussion of a paper by Dr. Thallon, in the *Brooklyn Medical Journal* for January, 1888.

The Treatment of Furuncles by Intestinal Antisepsis.—Bouchard, in *L'Union Médicale*, of January 21, 1888, reports good results in general furunculosis from

Naphthol (β)
Bismuth. salicylat.
Magnesiæ, ... āā gr. 5.

repeated four times daily.

A Hairpin in the Peritoneum.—Dr. Freund, of Strasburg, describes in the *Centralblatt für Gynäkologie* of December 17, 1887, a case where a hairpin was found in the peritoneal cavity in the course of an exploratory operation for suspected disease of the uterine appendages. The patient was a sickly and emaciated woman, aged forty-one, who had symptoms of tertiary syphilis. Her periods had been regular till about four months before she first applied for hospital relief; then they did not appear for two months; at the end of that period metrorrhagia set in, with the discharge of small shreds, and spasmodic pains in the sacral region and the hypogastrium. The discharge of blood continued for five weeks, then epileptiform fits occurred. The uterus was found anteverted, and a small oval tumor lay to its left side, connected by a tough cord with the pelvic wall. Tubal pregnancy was suspected. On March 2, 1887, an exploratory incision was made; the adhesions, which bled freely, had to be broken down, and a cyst of the left tube, "the size of an apple," was removed. It was universally adherent to surrounding structures; and, in securing some bleeding vessels to the great omentum, a piece of hairpin, an inch long, and consisting of part of the two shanks pressed close together just below their point of union, was discovered and extracted. A drainage-tube was left for twenty hours in the wound. The patient did well for a fortnight, then the stump of the tubal pedicle suppurated, and the pus which escaped contained ligature-threads. The first period after operation was attended with attacks of convulsions, which lasted eight days; but the second was only represented by the molimen without show, and by slight convulsive attacks. Ten days later a hard substance was detached, on vaginal examination, to the left of the cervix. The woman was in good health when last seen by Dr. Freund; but there were slight convulsions at every menstrual period. Should a portion of the hairpin yet remain in the pelvis, the persistence of the neurosis is readily comprehensible; should the hard body be simply an inflammatory deposit, the persistence of the symptoms would be a feature already observed in other cases, where self-evident causes of nerve irritation have been removed, the neurotic condition remaining for a long time after their removal. It appears that in this case the shanks of the hairpin had been pressed together, and introduced into the uterus for the destruction of an imaginary fœtus, amenorrhœa having followed cohabitation. The pin had broken, found its way into the left tube, set up salpingitis, perforated the tube, and reached the omentum. Dr. Freund shows, on carefully considered evidence, that the prevalent theory that hairpins are introduced into the genito-urinary tract, either in the belief that the practice may procure abortion, or for another repulsive purpose, is perfectly correct.—*British Medical Journal*, February 18, 1888.

Formulæ for the Use of Drugs by Atomization in Phthisis.—Dr. Bruen, in the *Therapeutic Gazette* of February 15, 1888, reports his method of treatment as follows:

The apparatus which is most satisfactory to me is the vaporizer of Codman & Shurtleff, of Boston. This firm supplies an atomizing apparatus placed in a flask, and the atomizing force is supplied from a gasometer capable of retaining air at the pressure of twenty-five pounds. The compressed air can be supplied by other forms of apparatus, as the Burgess apparatus; the essential principle being to use a dry vapor, which must be inhaled under a certain pressure, say from fifteen to twenty-five pounds. I have found great satisfaction in using one of three formulæ:

a. ℞.—Carbolic acid. . . . gr. xvj.
Compd. tinct. iodine . . ♏ xvj.
Glycerin . . . . ʒ ss.
Water . . . . ʒ ij.—M.

b. ℞.—Terebene . . . . ℥ss.
Fluid cosmoline . . . ʒj.—M.

c. ℞.—Paregoric . . . . ʒiij.
Ethyl iodide . . . . ℥ss.
Chloroform . . . . ʒj.
Fluid cosmoline . . . ℥ss.—M.

The first of these solutions seems to be most beneficial in the form of bronchial and lobular desquamative catarrh, combined with softening and apex cavity. Frequently in such cases the temperature can be promptly reduced within an hour after inhalation. When the treatment has been followed steadily, the effect is to modify the processes of bronchial catarrh, suppuration, and softening, and to lessen cough and expectoration, to diminish night-sweats, and most decidedly to influence the temperature. The creasote vapor sometimes produces a sensation of dryness, or irritation of the bronchial mucous membrane, which may necessitate its temporary suspension.

When the cough is very dry and troublesome the vapor of the iodide of ethyl is soothing, or I have found that the following formula, used on the Yeo inhaler, is very efficient:

℞.—Ethyl. iodidi . . . . . ʒ iv.
Chloroformi . . . . . ʒ j.
Tr. opii camph. . . . . ʒ iij.—M.

Sig.—Ten to twenty drops every half-hour for one or two hours several times daily.

I have used the foregoing formula sufficiently often to enable me to speak with precision as to its value, but I have also used the same apparatus in a number of cases

with other combinations, such as fir wood oil, one part, and fluid cosmoline, two parts; or the following:

R.—Tr. iodinii comp. . . . . ♏ vij.
Tr. conii . . . . . ♏xv.
Glycerinæ . . . . . ℥iv.
Aq. . . . . ℥iv.—M.
Use in vaporizer.

R. Acid. carbolic. . . . . ℈ j–℥ vij.
Sodæ biborat. . . . . ℥ ij.
Glycerinæ . . . . . ℈ ss.
Aq. dest. . . . . ad ℥ iv.—M.
Filter and use in vaporizer.

The Antiseptic Value of Naphthol.—MAXIMOVITCH, in recent experiments, found that alpha-naphthol is less toxic than beta-naphthol, of greater antiseptic value, and that the amount necessary to intoxicate a man of ordinary weight is about one pound.—*Gazette Hebdomadaire*, February 10, 1888.

Zooplastic Grafts. — Surgeons are familiar with skin grafting in the human subject, but it is rather a novel procedure to substitute the skin of birds and poultry for snips from the patient's own healthy skin. Wiesmann twice transplanted skin from pigeon to pigeon with success, and three times from fowl to fowl. Under the title of *Dermepenthesis*, Mr. G. F. Cadogan-Masterman published some interesting cases a few weeks since in our columns, in which he had succeeded in utilizing the skin of young wild rabbits for the purpose of bringing about the cicatrization of raw and ulcerating surfaces. Several others have repeated and varied Wiesmann's experiments, but before Mr. Masterman none of them seem to have been enterprising enough to spare their patients the disagreeable snipping incidental to the operation as it is usually practised. At about the same time Dr. Redard communicated to the Paris Academy of Medicine some observations of his own with animal grafts on wounds in human beings. In a case of severe burn of the scalp of eight months' standing, in a child two years of age, he obtained rapid cicatrization by means of grafts from a fowl. He first tried grafts of frog's skin, but as these proved to be repulsive to patients, and did not give very good results, he substituted others from the fowl, and the wound, which measured three inches by two and a half, had completely healed in two months. He had been equally successful in other and subsequent cases. He takes the skin from beneath the wing of a chicken, carefully securing the subjacent cellular tissue, but avoiding adipose tissue. The transplanted pieces varied from a sixth to a third of an inch in size, and they were maintained in position by means of a little cotton-wool and iodoform gauze. The skin of birds and fowls has the advantage of being supple, delicate, and vascular; it adapts itself readily to the surface of the wound, and adheres without undergoing absorption.—*British Medical Journal*, February 18, 1888.

Saccharin in Diabetes.—PURDY, of Chicago, concludes as follows from his clinical observations upon saccharin, in the *Journal of the American Medical Association* of February 25, 1888:

First. That in this product we possess a flavoring agent for food and drink the palatability of which is quite equal to that of the finer grades of sugar, and which may be used by diabetic patients with the greatest impunity.

Second. That through its antiseptic properties it retards the abnormal fermentative changes in the stomach so common in diabetic patients—thus promoting digestion and relieving flatulence.

Third. That while as yet we are without sufficient practical data to judge of its blood effects in large doses to diabetic patients, yet both chemistry and physiology would indicate its use for the purpose of favorably influencing some of the more fatal complications of the disease.

What is a Stone in the Bladder?—SIR HENRY THOMPSON describes the calculi which he considers "stone in the bladder" as follows, in a communication to the *British Medical Journal* of February 18, 1888:

I venture to think that twenty grains is the very lowest weight, in the adult, the removal of which should be esteemed an operation for stone in the bladder. And in chronic prostatic retention cases, where the phosphatic concretions so frequently and so rapidly form, I have never recorded anything as a stone which has not reached at least half a drachm.

There is another aspect of the matter, too, which cannot be lost sight of. I think that it is very undesirable, from more than one point of view, to convey an impression to any patient from whom a bit of gravel weighing two or four grains has been removed that he has undergone operation for stone in the bladder, and that the custom might give support to objectionable practice.

I beg to submit these remarks to the consideration of my professional brethren, in the belief that it is desirable to have some general understanding as to the meaning of the term in question, and to adopt, if possible, a uniform method in the employment of it in future.

The Treatment of Cold Abscesses by Iodoform in Ether.—HOLSTEIN, in a recent Paris thesis, reports that in Verneuil's clinic in Paris, tuberculous abscesses have been treated for two years with iodoform dissolved in ether, with excellent results. Of 20 cases 11 were cured, 6 improved, and 3 unimproved by this treatment. After aspirating the contents of the abscess from two and a half to twelve and a half drachms of a 10 per cent. solution were injected once; in large abscesses as much as twenty-five drachms of a 5 per cent. solution were injected. If the ether proved irritating it was injected through an hypodermatic syringe. This method is especially useful where it is desired to avoid a scar.—*Centralblatt für Chirurgie*, No. 4, 1888.

Antisepsis in Ophthalmology.—SCHMEICHLER, in reviewing the advances of antisepticism, quotes the statistics of Arlt, 1700 cataract operations in eight years with a percentage of bad results of 2.06 per cent.; also Gräfe, at Halle, who performed 426 cataract operations without a bad result. He considers affections of the conjunctiva and tear sacs especially fitted for antiseptic treatment, and recommends solutions of corrosive sublimate and emulsions of iodoform, in varying strengths, for this purpose. Mercurials are to be used in 1 to 2000 and weaker solutions; the iodoform emulsion should be ten per cent. —*Präger med. Wochenschrift*, February 8, 1888.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,

Per Annum, in Advance . . . . . $5.00.

Single Copies . . . . . 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia.

SATURDAY, MARCH 17, 1888.

ACUTE RHEUMATISM.

In a recent Report of the Collective Investigation Committee of the British Medical Association (*British Medical Journal*, February 25, 1888) Dr. Whipham has analyzed 655 cases of acute rheumatism, chiefly sent in by country practitioners, to which class the profession is largely indebted for the valuable material composing the previous reports of this Committee.

Of the cases, 57.25 per cent. were males, and 42.25 per cent. were females. It is interesting to note how few cases were in children under ten years old, only 32 in all; 80 per cent. of the cases occurred between the twentieth and fortieth years. Of occupations, that of domestic servant heads the list with 71 cases, which Dr. Whipham attributes in part to the inordinate consumption of alcoholic drinks to which persons in this station of life are addicted, and also to the want of proper exercise with its consequent accumulation of nitrogenous compounds in the tissues. To this should be added a still more important factor, the damp, ill-ventilated rooms in which persons of this class pass a large proportion of their time.

Very careful inquiries were made as to the habits of those attacked. An elaborate analysis is given of the course and complications in the three classes —teetotallers, temperate, and intemperate persons. It is stated that on the whole the figures are in favor of the teetotallers, except in three important points: first, the average duration of the attack was 23.6 days in the intemperate males against 25.27 days in temperate males and 27.26 days in teetotallers; secondly, the percentage of deaths in teetotallers is more than double that of temperate persons; and, thirdly, the percentage of heart affections is in teetotallers 51.41 against 40.59 in temperate and 46.87 in intemperate males.

The general opinion that rheumatism is more prevalent in low, damp localities is not borne out by the figures, for by far the larger number of cases occurred in high, dry, exposed regions. More than 47 per cent. of the cases occurred when the atmosphere was damp, cold, and cloudy.

Of antecedent illnesses 24.12 per cent. of the patients were the subjects of tonsillitis, 13.43 per cent. had had scarlet fever, 2.59 per cent. had suffered with anæmia, and in only 1.98 per cent. was chorea either antecedent or concomitant. Considering the close relationship believed to exist between rheumatism and chorea, it is rather remarkable that in such a large series of cases, 655, there should have been only 13 instances of chorea. Of recent antecedents to the rheumatic attack, exposure to cold and wet, particularly when combined with over-fatigue, were the most frequent, occurring in 366 cases. Over-fatigue alone, either sudden or prolonged, was present in 64 cases.

A very full analysis is given, illustrating the influence of treatment on the fever, the pain, and the duration of the attack. There were seventeen different combinations employed, into fourteen of which the salicin compounds entered. The favorable effect of these remedies is shown in shortening the period of fever, in lessening of the pain more quickly, and in reducing the duration of the attack. The largest number of cases were treated with the salicylate of sodium or potassium, and the average duration of the fever was 8.65 days; of the pain, 10.18 days; and of the whole attack, 19.03 days. Of the total number, 655 cases, 536 were treated with salicin compounds, and in only 22 cases did they fail; in this number the salicylates failed in 16 cases.

Of cardiac complications, pericarditis and endocarditis occurred synchronously in 57 cases, and in 54 cases pericarditis occurred alone, making a total of 111 cases, 16.94 per cent., in which the pericardium was involved; of these cases 6 died. In 77 cases heart murmurs developed, which disappeared with recovery, and in 128 the murmur originating in the attack persisted. The mitral systolic murmur was present in 94 of these cases. Of other compli-

cations, pneumonia and pleurisy were the most frequent, 11 cases of the former and 13 of the latter. Hyperpyrexia occurred in 4 instances, 3 of which proved fatal. In 1 case the temperature rose to 110° on the twenty-first day.

Seventy patients suffered relapse; it was impossible to say whether or no the treatment had any influence in this respect, though over 97 per cent. of these cases were taking the salicin compounds.

Death occurred in 22 cases, 3.30 per cent., in the majority of the cases with cardiac complications.

A special value is attached to these reports of the British Association, as the returns are sent in, as a rule, by family practitioners, and we are in this way gradually acquiring statistics of disease in private practice.

THE FOURTH YEAR AT HARVARD.

As endowments increase, the establishment of a compulsory fourth year in medicine is only a matter of time with the great schools of medicine in this country. Meanwhile it is interesting to study the tentative efforts in this direction, and the report of President Elliot, of Harvard University, as analyzed in the *Boston Medical and Surgical Journal* of February 16th, supplies us with some interesting facts.

Since 1881, when the optional fourth year was established with a special degree *cum laude*, the number of students taking this course rose gradually from ten in the first year, to twenty-one in the session of 1886–87. It has been found, however, that not one-half of those who take the fourth year apply for the degree *cum laude*, while of those who do, the percentage of rejections is very high, 35, against 16½ per cent. for the third year degree.

One reason, we suppose, why so few apply for the degree *cum laude* is that they already possess the ordinary doctorate, and from various causes (of which, from the high percentage of rejection, fear of failure may be one) give up the attempt. Our contemporary notes that the fourth year is naturally made up of two sorts of men, the specially good student and the indifferent ones, who need four years' study to obtain the third year degree. In the analysis no attempt has been made to separate the second class. It would be interesting to know how many of the applicants for the fourth year degree had been rejected at the third year examination.

The advantages of a fourth year cannot be judged in this way any more than those of a third year can be estimated in schools in which it is optional. Perhaps it is the best which can be done at present, until the public arouse to the necessity of endowing medical colleges. There is nothing in the report in the slightest degree discouraging to the friends of higher medical education, and could the financial difficulty be met, the Harvard School might solve the problem of the fourth year. Indeed, the prospects to-day, should an obligatory fourth year be added, would be much brighter than they were in 1871–72, when Harvard boldly advanced the curriculum to three sessions of nine months. To timid professors and trustees of medical schools we would advise a course of reading of President Elliot's Reports of 1872–73 to 1886–87 inclusive.

THE PHILADELPHIA HOSPITAL.

THE recently issued Report of the Department of Charities and Correction contains a very full statement of the position and prospects of this institution. The new Board of Directors under Dr. J. W. White has continued the good work started under the recent management, and has made several important changes, notably bringing the Insane Department and the Women's Out-wards under the Executive of the Hospital. The Board seems fully aware of the urgent necessity for making additional provision for the paupers, and urges again the separation of the Almshouse from the Hospital, and its removal to another locality. This would give the room urgently demanded for the accommodation of the convalescents who are now herded in attics in a manner disgraceful to any civilized community. The Board has done its duty in boldly stating it to City Councils, with whom now rests the responsibility for this lamentable state of affairs. As the report states: "In these attics are congregated so many individuals that the two thousand cubic feet of space which, according to the best authorities, is essential to each, is reduced to an average of about three hundred feet. When the beds are prepared for the night there is barely room enough left to enable one to walk from one end of the room to the other. Many of the patients are compelled to sleep two in a bed!" A single nocturnal visit by the Mayor and Councils to the attics of the Philadelphia Hospital should suffice to secure appropriations amply sufficient to remove at once this deep disgrace.

THE Second Congress of the German Society for Gynecology will meet at Halle, May 24–26, 1888. Communications should be addressed, before April,

to Professor Kaltenbach, at Halle. The meeting will be under the leadership of Kaltenbach, Olshausen, and Gusserow.

The *Albany Medical Annals* for February appears in a new dress, and under the editorial management of a new committee, namely, a committee of editors appointed by the Library and Journal Association, recently inaugurated in Albany. The important subject discussed before the local medical society in December last was the dangers of tonsillotomy, and it is well reported in the February number. Dr. Blair narrated two cases of serious, though not fatal, hemorrhage following the use of the tonsillotome.

The American Anthropologist, edited by a Committee of the Anthropological Society of Washington, has recently appeared for the first time. It is a magazine of nearly a hundred pages, containing articles of value to those interested in anthropology.

The publication of the *Berliner Klinik*, under the editorship of Hahn and Fürbringer, and also of the *Wiener klinische Wochenschrift*, is announced in Berlin and Vienna, respectively.

The Cartwright Lectures for 1888 of the Alumni Association of the College of Physicians and Surgeons of New York will be given at the College by Prof. William H. Welch, of Johns Hopkins University, on Thursday evenings, March 29th, April 5th and 12th, at 8.30 P. M. The subject will be the "General Pathology of Fever."

Assistant Surgeon James E. Pilcher, U. S. A., will read a paper on "The Transportation of the Wounded," before the Military Service Institution, at Governor's Island, New York Harbor, next Tuesday, at 2 P.M.

The Long Island College Hospital, at its commencement last week, conferred the degree of M.D. on thirty-six graduates.

The Medical College of Ohio conferred the degree of M.D. on seventy graduates. Dr. John S. Billings, U. S. A., a graduate of the class of 1860, delivered the Address to the Alumni.

Dr. Henry F. Lyster, of New York, has been appointed to the chair of the Practice of Medicine in the Michigan University.

Dr. Lewis A. Stimson has been appointed one of the Surgeons to the New York Hospital.

Dr. Henry B. Sands has tendered his resignation as Surgeon to Roosevelt Hospital.

Seaman, of Howard University, Washington, has secured information from more than twenty American colleges, regarding the kind of microscopes used and the results of wear. The answers were, in a large majority, in favor of microscopes of American manufacture.

The Saturday and Sunday Hospital Fund of New York City collected this year $50,400, or about $2600 less than last year. This sum will be distributed among twenty-four hospitals and dispensaries, in proportion to their amount of days of care of free patients. The Mount Sinai and St. Luke's hospitals will get about one-third of the receipts. The cost of distributing this charity is about $2600 yearly.

The Metropolitan Fund of London this year received £39,000, which has to be divided among 150 hospitals and dispensaries, with the exception of four per cent. of the amount, which is set apart for the purchase of surgical instruments and appliances for crippled persons.

It is estimated that one-half of all the drugs imported into the United States is consumed in the manufacture of patent medicines.

In New York State there were sixty-five convictions of illegal medical practitioners during the year 1887.

A mind-healer, named Teed, has been arrested in Chicago, consequent upon the death of a patient by pneumonia, the coroner's jury making declaration that the death was attributable, in part at least, to the lack of proper medical treatment. The accused will be tried for practising medicine without a license, an offence against the laws of the State.

According to the recent publication of Bonbrow, Medical Director at St. Petersburg, the mortality, in some localities in Russia, is 60 or 80 to 1000; among children it rises to 60 or 80 in 100.

There are, on this basis, 2,800,000 deaths in the Russian Empire yearly, 500,000 of which are due to imperfect sanitation.

REVIEWS.

Fever Nursing. By J. C. Wilson, A.M., M.D. 12mo. pp. 210. Philadelphia: J. B. Lippincott Co., 1888.

This most recent member of the series of Practical Lessons in Nursing is written by one who has already shown his knowledge of fevers in his *Treatise on Continued Fevers*. In accordance with this, the continued fevers receive full attention; while pyrexia in general is considered at some length, septic fever is not mentioned as such, and the mind of the nurse is directed to the fevers treated by the physician. As the fever of sepsis is not described in *Maternity and Childhood*, it evidently awaits the volume on Surgical Nursing.

"Fever Nursing in General," almost the first half of the book, treats fully of the care to be given the patient suffering from any non-septic fever. The experience of the author has been in support of baths and packs of *cold* water; he has apparently not met with the writer's experience, who found in several cases of hyperpyrexia attended by marked nervous prostration that cold applications produced only increased prostration, while hyperpyrexia yielded to sponging with *hot* water, to which a little alcohol had been added. These cases are certainly not common, but we believe sponging with a warm, or even hot fluid, an efficient reducer of temperature, when practised with suitable discrimination.

The nursing of the continued fevers is admirably described. Symptomatology is treated so distinctly that she must be a dull nurse who does not obtain a clinical picture of these diseases of great value.

In treating of the contagion of diphtheria Dr. Wilson speaks with such refreshing force regarding the conduct of the apparently healthy members of the household that we wish his words could be in the possession of every household in the country. He says, "The well, or apparently well members of the household must not attend church, places of amusement, or other public places of assemblage, nor pay or receive visits. The children must not be allowed to go to school." If such isolation of infected households were commonly practised, epidemics of diphtheria would be less frequent. The author's "Fever Charts," illustrating typical cases of the most common fevers, are appended.

In Dr. Wilson's *Fever Nursing* the best work done in the scientific care of the sick receives a full and attractive exposition, and we cordially commend the book, not only to nurses but to physicians, to whom it will be a useful memorandum of points of practical importance.

SOCIETY PROCEEDINGS.

THE PHILADELPHIA NEUROLOGICAL SOCIETY.

Stated Meeting, January 23, 1888.

The Vice-President, Charles K. Mills, M.D., in the Chair.

Dr. F. X. Dercum reported

A CASE OF CHOLESTEATOMA, WITH REMARKS ON THE ORIGIN OF THE TUMOR.

P. J., aged forty-three, unmarried, an Englishman by birth, was admitted to the nervous wards at the Philadelphia Hospital on August 3, 1887. He was dull and stupid. He answered questions slowly and imperfectly, and gave a very poor and disconnected account of himself. He said that about nine years ago he had had a wen removed from his scalp at the German Hospital. Otherwise he had been in good health.

Careful examination of the scalp failed to reveal any evidence of a former operation, and an exhaustive search among the records of the German Hospital failed to reveal any history of it.

His present trouble had commenced about three months ago, with trembling of the hands, and more or less mental confusion. He had what he called a "rigmarole of things" in his head. On admission, he complained of constant and persistent headache, which he invariably referred to the base and the back of the skull. He was, in addition, quite weak, but in no sense paretic. Sensation seemed to be normal. The knee-jerks were markedly increased. An examination of the eyes revealed double optic neuritis. The pupils at this time showed no decided inequality.

Brain-tumor was deemed probable, but, owing to the absence of special symptoms, it was not possible to locate the lesion. There had at no time been any localized palsy, any convulsion, or, in fact, any symptom referable to this or that part of the cortex.

The patient was under constant observation up to the 31st of August, when he died. During this time his mental condition gradually grew worse. He became more and more stupid, and at times wandered. On the day of his death he commenced vomiting, the vomit consisting merely of mucus and bile. He rapidly became less and less conscious, and finally lay perfectly quiet, with the exception of occasional movements of the head and arms. These movements were, however, not in any way convulsive. When the hands or arms were pricked with the æsthesiometer he would draw them away, but further than this he could not be aroused. His right pupil was now seen to be widely dilated, while the left responded but sluggishly to light. His pulse was 64, soft, and compressible, and his respiration was 28. His general appearance was that of a man in a sound sleep, but whose face was flushed. Toward evening his depression deepened, and at 7.20 P.M. he died.

At the autopsy it was found necessary to remove the brain entire with the calvarium, all of the tissues, the brain, dura, and bone being very much adherent to one another. An examination revealed this adhesion to exist in an area some two or three inches in diameter in the right frontal region. In forcibly separating the dura from the bone a rough prominence was discovered on the latter, occupying the middle of this area. The prominence measured about two-thirds of an inch across, and about one-sixteenth to one-eighth of an inch in height. The outer surface of the calvarium revealed no change other than a slight deepening of color—a faint purple tinge—at the site corresponding to the prominence on the inner side. The dura mater, on the other hand, exhibited a depression, a shallow pit, the counterpart of the bony prominence. Beneath this pit, and for the radius of an inch or more around, the tissue felt much firmer than normal, and a rounded mass was readily outlined by the finger. On attempting to raise the dura it was found to be intimately united with the underlying tissue, not only over the tumor, but also over the entire

vertex. The pia, in turn, was everywhere intimately adherent to the cortex. Its meshes were quite œdematous, as was also the brain substance. Some of the convolutions, especially at the base, were much swollen. The walls of the ventricles were exceedingly pale. The right lateral ventricle was much compressed. The choroid plexuses were cystic. The vessels at the base were apparently healthy. The veins of the pia were quite full.

The tumor was found to be situated between the first and second frontal convolutions on the one hand, and the anterior central on the other. It had developed downward, and gradually separated these convolutions. The pia was intimately adherent to the edge of the growth, and did not separate it from the brain substance. A number of vessels could be seen passing from the former directly into the latter. When incised the tumor had a whitish or pinkish-white color. It was quite friable, and a pinkish-white juice could be expressed from it.

The microscopical examination reveals its general structure to be that of a sarcoma, while scattered through it in varied profusion we find typical, pearly bodies.

Dr. Dercum had not been able to find in the literature of endotheliomata or cholesteatomata an exactly similar case. The formation of the pearly bodies in the midst of a sarcomatous tissue is exceedingly interesting, especially in the present instance, as the locality of the tumor gives abundant opportunity for the origin of the endothelioid formations. They closely resemble the pearly bodies of the epitheliomata, so much so that some writers still believe them to be of epiblastic origin. Their occurrence, as in the present instance, in the depth of a sarcomatous tissue, is certainly another argument against this view.

On examining them closely their concentric, onion-like structure is readily seen. Their centre appears to be made up of a granular and nuclear material which is probably cell-detritus. Toward the periphery individual cells, more or less preserved, are still to be distinguished. They are sharply differentiated from the surrounding tissue; though the vacant space seen about them is probably the result of the hardening process.

Clinically this tumor is interesting from the absence of symptoms enabling us to localize it. Dr. Dercum's impression was that it was either far forward in the frontal region or back somewhere in the occipito-temporal region, not interfering with the cuneus. He favored the latter supposition on account of the basal and occipital pain. He regretted that the scalp was not shaved in order that evidences of traumatism could have been better sought for.

The man had an exostosis on the inner table of the calvarium involving the upper portion of the frontal bone somewhat in advance of its junction with the upper portion of the right parietal. There had been inflammation of the dura about the exostosis, with adhesion to the pia. From this focus of irritation the tumor appears to have developed.

Dr. William Osler said that a short time ago he reported a case in which the pearly bodies were even more distinct than in the specimen shown and in which the origin from the endothelium of the floor of the third ventricle and infundibulum was evident. In this tumor, as in Dr. Dercum's, there were many spindle-cell elements. Cholesteatomata are more common at the base than on the cortex.

Dr. Charles K. Mills said that Dr. Dercum's case is of interest as bearing upon the localization of growths in the second frontal convolution. In the case on which Dr. Keen operated, the tumor was in much the same position, perhaps a little lower. In a case which he reported to the Pathological Society the tumor was situated in much the same locality. In all these cases there were eye symptoms. In his own case he noted a certain fixity of the eyes with dilatation of one pupil. These cases to a certain extent carried out the idea of Ferrier and others that the oculo-motor centres are located in the second frontal convolution.

Dr. Dercum said that his patient had no specific symptoms of the locality of the tumor. He did not place the same interpretation upon the eye symptoms as did Dr. Mills. This tumor did not press directly upon the cortex, nor did it irritate the cortex. The man was killed by œdema of the brain and not directly by the tumor itself. The mass grew downward between the first and second frontal convolutions and the ascending frontal, and it separated these so gradually that no irritation was produced. The eye symptoms were of late occurrence. The tumor became so large that the venous return was interfered with and the brain became œdematous and was so found at the post-mortem. As a result we should expect oculo-motor symptoms from transmitted pressure. The size of the tumor was probably also increased by œdema. The right half of the brain was not as œdematous as the left, as it had not so much room to swell. The left base was much swollen.

Dr. Osler presented

A CASE OF LOCAL SYNCOPE AND ASPHYXIA OF THE FINGERS.

The patient came to the Infirmary for Nervous Diseases a few days ago with her hands in the following condition. The second, third, and little fingers of the left hand were like marble, the line of demarcation being at the second joint. The thumb and index fingers with those of the right hand were livid, particularly the terminal phalanges. The condition is aggravated by exposure to cold. The local syncope is so marked that he thought the members would be interested in it. The condition is variable, the syncope in a short time is followed by asphyxia. This is the mildest grade of Reynaud's disease, which in extreme cases may result in gangrene of the affected finger-tips.

He thought that the local syncope is caused by vasomotor spasm. Following this there is relaxation of the spasm with extreme engorgement. Such a condition produced by the local action of cold is closely related to chilblains. Many of these cases have had chilblains. Last winter he had at the University Hospital a child, aged thirteen or fourteen, who had presented for many years this condition of local asphyxia of the terminal phalanges of both hands. It did not vary in any degree while under observation.

Dr. Edward N. Brush reported

A CASE OF PORENCEPHALUS, WITH SPECIMEN.

J. K., aged fifty-seven, a native of Pennsylvania, married, by occupation a laborer, was admitted to the Pennsylvania Hospital for the Insane, June 16, 1885.

The following is an abstract of the history of the case: At birth the patient was observed to be unsymmetrically developed. The left side was smaller than the

right, the limbs were shorter and their circumference less. No history of infantile paralysis could be obtained, and the patient is said to have walked at about the usual age, though with a limp which continued through life, owing to the shortness of the left leg.

At the age of nine, while playing in a barn he fell to the floor from the hay-loft a distance of some sixteen feet, striking the back of his head. For some weeks following this fall he complained of headache, but his general health did not seem to be affected.

As a young man he was intemperate in the use of liquor, but he had been for some years prior to admission of temperate habits.

A maternal uncle had been insane and several relatives are said to have died of "dropsy of the heart."

About nine years before admission to the hospital he had sunstroke, and was from that time frequently troubled with severe headache, especially during the hot weather.

He had always been a man of violent temper and rough in conversation, and, following the sunstroke, is said to have become worse in these respects. By some he was regarded as not possessing a thoroughly balanced mind. His friends had not noticed any active mental disturbance earlier than a week prior to his admission to the hospital, when he suddenly became noisy and violent, and gave expression to extravagant delusions. His condition, however, on admission pointed to a much longer period of mental disturbance, as he was in advanced general paresis. Upon inquiry, it was found that as early as December he had been talking in a boastful manner of his power and possessions, and particularly of the speed of his horse. It was also found that he had not, on account of his imaginary wealth, made any charge for his services as a carter since spring.

On admission he walked with a slight halt, the left leg was shorter than the right—as was also the left arm; there was some asymmetry of the skull, particularly in the occipito-parietal portions—the left arm was stiff from an old fracture. In addition to the limp, his gait was somewhat ataxic. He swayed to a marked degree when standing with his eyes shut. The tendon (patella) reflexes were absent. The pupils were unequal, the left being the smaller. They responded to light very slowly, and not at all to accommodative changes. No other examination of the eyes was made at the time, and the patient was never in a condition subsequently to permit any. There was commencing cataract in each eye.

The patient gave expression to very extravagant delusions of wealth, and was lavish in his gifts of checks to all about him.

There was marked tremor of the lips and tongue, and of the hands and fingers as well. He pronounced his words in a hesitating, drawling fashion, and frequently stumbled over words of many syllables.

The case progressed without incident for some weeks. He was frequently noisy, shouting and singing. His gait grew more disturbed—he manifested a tendency to fall forward, and, when once started, would almost run at times to keep from falling. At the end of a month his pupils had become almost pin-points. His speech was more hesitating and his delusions more extravagant. He said that he had a horse which could trot a mile in a minute and a quarter less than no time—and another that could go around the earth in two minutes and a quarter. He had hallucinations of sight and hearing.

For a time the patient gained in flesh, but soon lost and in the fall was quite emaciated, though eating heartily. The tendency to fall forward continued, and it became necessary to support him in walking. When he could be induced to stand still, he was able to support himself fairly well.

To omit unnecessary detail, it will suffice to say that the patient became noisy, untidy, and very destructive of clothing—at the same time failing mentally and physically. In November, five months after admission, he was quite demented, and his speech was hardly intelligible.

On December 2, 1885, the ward notes state that his morning pulse was 48, temperature 97°; P.M., pulse 56, temperature $97\frac{8}{10}°$, in bed quite feeble. On the day previous he had been up and had taken some exercise in the ward with the assistance of an attendant.

December 3d: A.M., pulse 60, temperature $97\frac{8}{10}°$; P.M., pulse 64, temperature 98°. Heart sounds muffled. Respiration 14.

December 4th: A.M., respiration blowing, 10 to 12; pulse 48, face pale, body generally blanched; is comatose. At 2.30 P.M. the respirations were but eight per minute and wholly diaphragmatic; pulse 54. Died at 8.15 P.M.

Autopsy sixteen hours after death. Examination made of brain only. On removing the calvaria the dura in the right occipito-parietal region protruded, bulged out as if from internal pressure. Dissecting the dura carefully from the brain, to which it was strongly adherent over the vertex, this protrusion was seen to be due to a large accumulation of serum beneath the arachnoid. In removing the brain, the arachnoid was accidentally ruptured and the fluid escaped. About six fluid-ounces were collected and found to differ in no respect from the ordinary cerebro-spinal fluid.

Enlarging the opening in the arachnoid the cavity which is shown in the specimen was found. It will be observed that it communicates with the lateral ventricle, the posterior cornu of which is enlarged, and that it is lined, except where it communicates with the ventricle, with the pia mater. This cavity, it will be observed, occupies the position of the parietal lobe and encroaches also upon the occipital and temporal.

The ascending parietal convolution is, in its upper portion, almost wholly absent, a small amount of cortical substance held in the meshes of the membranes alone remaining.

The superior parietal lobule, or a portion of it rather, forms the roof of the cavity. Nothing of this lobule remains but a mere shell of cortical substance and membrane which overhangs the cavity.

The posterior portion of the superior temporal convolution is absent and nothing but a thin membrane exists between the cavity and the fissure of Sylvius, which is turned abruptly upward. The inferior occipital convolution appears intact, but of the superior and middle only a small portion remains.

On the inner surface of the hemisphere the cuneus is simply represented by a shell of brain substance, and of the quadrate lobule nothing remains but a thin stratum of brain substance at its anterior portion.

If the right hemisphere is compared with the left, the portion not encroached upon by the cavity is markedly smaller, and the convolutions are not as well developed.

The difference in weight between the two hemispheres was, when removed and thoroughly freed from fluid, nine and one-eighth ounces.

The cerebellum has developed unsymmetrically, the right half extending upward and forward considerably in advance of its fellow, owing to the absence of resistance from the right cerebral lobes. It is to be regretted that the maniacal state present at the admission of the patient, and the subsequent dementia into which he passed, prevented a more careful clinical study of the case, and especially that no opportunity was afforded for recording the eye symptoms.

Dr. E. T. Bruen also presented a specimen from a

CASE OF PORENCEPHALUS.

The specimen of the brain which was presented was removed from the body of Mary C., æt. thirty-two, who died in the Philadelphia Hospital September 21, 1887. On removing the dura mater four cysts were found situated upon the cortical portion of the brain near the occipital lobes of both sides.

There were two cysts on each side of the median fissure, those on the right side were irregular in shape, and somewhat larger in size than a walnut. They were situated mostly over the occipital lobe, but the outer one particularly extended over a portion of the parietal lobe. In the left cortex the cysts were much larger, the one close to the longitudinal fissure extended forward three inches, and was an inch in diameter. The smaller cyst was two inches long by three-quarters of an inch in diameter. The inner and larger cyst extended over the occipital and parietal lobes, parallel with the longitudinal fissure. The outer and smaller cyst occupied a position over the occipital lobe, but extended somewhat over the parietal lobe. The walls of the cysts were composed of thin lamina of membrane, and contained a clear fluid. Owing to the pressure occasioned by the cysts, extensive atrophy of the convolutions of both occipital lobes had occurred, but upon the left side the convolutions of the superior portion of the parietal lobe had also been decidedly involved in the atrophy consequent upon the pressure. This process was so marked that the surface of the left cerebrum was depressed half an inch below that of the right, and the entire left hemisphere occupied by the cysts appeared distinctly smaller. The close proximity of the cysts upon the left side to the fissure of Rolando, shows that the motor tract on this side of the brain must have been subjected to irritation by pressure during the development of the cysts.

Dr. Osler had seen several specimens of cysts in the brains of adults which were evidently, from the history, due to embolism or thrombosis, with secondary atrophy. Such defects may be large, and form examples of true porencephalus; but the condition which Heschel first accurately described, and to which Kundrat has devoted a large monograph, more often originates in fœtal life either in an error of development or as the result of disease. Encephalitis, obliteration of arteries, traumatism at birth, any condition, in fact, which in the fœtus or child leads to destruction of brain tissue, may produce porencephalus. Kundrat states that in the congenital cases the arrangement of the convolutions about the defect is radial. Bilateral lesion, as in Dr. Bruen's specimen, is rare, but the convex surface in the neighborhood of the motor zone is the most common seat. Intellectual defects and spastic paralysis are almost invariable associations when the condition is congenital or due to disease during infancy.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, February 17, 1888.

The President, James Perrigo, M.D., in the Chair.

Dr. William Gardner reported a

SUCCESSFUL LAPAROTOMY FOR PELVIC HÆMATOCELE,

due to rupture of the Fallopian tube in a case of extra-uterine fœtation. The patient, aged twenty-nine, was married in July last, and had an early miscarriage in October for which she was attended by Dr. Arthur Browne; after this she menstruated twice, the last time on the 2d of December. Toward the end of the month she had morning sickness for a few days. During the early part of January a bloody vaginal discharge appeared lasting nearly a fortnight. About the middle of January she was seized with violent pelvic and abdominal pains with most alarming collapse, during which for many hours she was almost pulseless. From this, in a few days she partially recovered, but soon there were recurrences of pain, faintness, and symptoms of peritonitis. Her physicians, Drs. Browne and George Ross, recognizing the nature of the case, requested Dr. Gardner's opinion, and after examination he fully concurred in their diagnosis of ruptured extrauterine fœtation. The next day the symptoms continuing alarming it was decided to open the abdomen. The right Fallopian tube was found expanded in a friable mass in which Dr. Johnston afterward found the fœtus embedded in clots. In attempting to ligature this Dr. Gardner tore it away. The pelvis was full of clots. These were scooped out and the cavity washed out with a forcible steam of water from Tait's large, blunt trocar carried to the dependent parts. A drainage tube was then inserted and left for eight days. For the first nine days the course of the case was perfectly favorable. Then evidences of cystitis appeared, and have continued to be rather severe. There seems no reason to doubt that recovery will ultimately be complete and permanent.

Dr. Gardner remarked that such a case as this illustrates well the triumphs of modern abdominal surgery.

Regarding this particular operation, we owe all that is worth knowing to Lawson Tait, whose remarkable results in a long series of such cases are now well known. The diagnosis is not always easy, but given sufficiently alarming symptoms the abdomen should be opened and the condition found dealt with as may be necessary. It is a great satisfaction to know that in the hands of competent surgeons the operation itself cannot be said to be a source of danger.

Dr. George Ross said he had seen this case in the early stage; when he was called to her she was almost pulseless and extremely pallid, but he did not regard her condition as by any means hopeless. He congratulated Dr. Gardner on the very successful result in this case, and said that, as far as he knew, it was the first case of the kind in Canada which had been treated by abdominal section.

Dr. Shepherd asked if it was not a fact that gynecologists look upon all cases of intra-peritoneal pelvic hæmatocele as due to a ruptured tubal pregnancy.

DR. GARDNER, in reply, stated that such is the opinion of Mr. Lawson Tait, but he considered it might be produced by other conditions, as, for instance, rupture of the ovarian veins, etc.

(The specimen, showing the fœtus embedded in the mass removed, was exhibited; also chorionic villi under the microscope.)

DR. GEORGE ROSS exhibited specimens obtained from a case of

CARCINOMA OF THE STOMACH AND LIVER.

The patient, aged fifty-five, had been under observation for four months and had never had any gastric symptoms, but suffered from profuse diarrhœa and had a haggard appearance. Examination discovered a hard mass in the left hypochondrium which moved with the diaphragm, the liver was not enlarged. There was no pain after eating and no vomiting. The diarrhœa was controlled and patient ate and drank well, but had continuous pain in the epigastrium. The hard nodule in the left hypochondrium rapidly increased in size and it looked as if the left lobe of the liver was the seat of the tumor, but its origin was always doubtful. Later the patient developed albuminuria and amyloid casts were found in the urine.

Patient gradually sank, and at the autopsy performed by Dr. Johnston there was found a large fungating cancerous ulcer occupying an area nearly four inches in diameter on the anterior surface and lesser curvature of the stomach; neither the pyloric nor œsophageal openings were obstructed. The base of the ulcer was deeply fissured and had extended into the inferior surface of the left lobe of the liver. There were no secondary deposits. Nature of growth chiefly scirrhus. The glands in the portal fissure of the liver, stomach, and intestines were in a state of amyloid degeneration. Kidneys and spleen amyloid but not enlarged. Dr. Ross said he had brought the case before the Society, not because it was a very rare one, but because it was important to recognize the fact that we might have most extensive disease of the stomach without having any symptoms referable to that organ. The occurrence of amyloid disease in these cases of malignant disease was rare so far as his experience went.

DR. MCCONNEL asked if it was not a fact that in carcinoma of the stomach there was always complete absence of hydrochloric acid.

DR. STEWART said that this idea was now refuted, as hydrochloric acid is absent from the stomach in many other diseases, and had been found where cancer was present in the stomach.

CALCULOUS NEPHRITIS.

DR. JOHNSTON presented for Dr. Bauer, of Waddington, N. Y., (1) a kidney affected with calculous disease. The entire renal substance was destroyed. The kidney consisted of a series of suppurating sacs, each containing a uric acid calculus coated over with phosphates. The other kidney was greatly shrunken and disintegrated apparently from pyelitis, but contained no calculi. The patient had had pyrexia for years and died of uræmic coma.

(2) A specimen of secondary

CARCINOMA OF THE PERITONEUM.

The growths, whose microscopical characters were those of encephaloid cancer, were all situated beneath the peritoneal coat of the intestines, soft and vascular and varying in size from a pea to an egg. The seat of the primary growth was uncertain.

DR. JAMES STEWART read a paper on the

PHARMACOLOGY OF ARSENIC.

He first dwelt on the mode in which arsenic kills in poisonous doses. Three cases of fatal arsenical poisoning were related in none of which were there any marked changes found in the gastro-intestinal mucus membrane after death. The first case was that of a girl aged nineteen, who was admitted into the Montreal General Hospital in September, 1887, six hours after swallowing two ounces of "Rough on Rats." There were constant retching, vomiting, and intense thirst.

The pulse was very rapid and weak; vomiting and diarrhœa, which latter soon set in, continued until her death four days after taking the poison. At the section performed by Dr. Johnston, twenty-four hours after death, there was found in the anterior surface of the stomach near the pylorus an elongated ulcer half an inch by one quarter, with firm, rounded, and undermined edges. The base, which consisted of the muscularis, was smooth. There was no hyperæmia in the neighborhood or elsewhere in the stomach. Beyond slatey pigmentation of the solitary follicles nothing abnormal was found in the intestines. In the case reported it was mentioned that everything pointed to the ulcer being "a chronic gastric ulcer," and that there was no evidence of any inflammatory action being set up by the arsenic.

The second case was that of a prostitute, aged thirty-five. She swallowed an unknown quantity of "Rough on Rats" on the 29th of September last. Eighteen hours afterward she was admitted into the Montreal General Hospital in a state of great depression. Her pulse was 150, weak, and thready, there was very profuse serous diarrhœa with occasional vomiting. She died thirty-three hours after taking the poison. There was an entire absence of any inflammatory symptoms in the stomach and intestines. Dr. Johnston, who performed the autopsy, found a large ecchymosis beneath the endocardium of the right ventricle.

The third case was one of arsenical poisoning from the application of a paste to a fungating epithelioma of the dorsum of the foot. The patient was a woman aged sixty. The prominent symptoms were purging and vomiting. Dr. Johnston, who performed the autopsy, could find no evidence of any inflammatory action in the stomach or intestine. Arsenic was found in all the internal organs, especially the liver. In this case the drug was absorbed into the blood from the wound and eliminated by the gastric and intestinal mucous membrane.

In all three cases death was brought about not by the violence of the inflammatory action but by the lowered blood-pressure. The reader of the paper went on to say that this lowered blood-pressure is generally attributed to paralysis of the splanchnics and that probably the best means to control it is to inject large quantities of fluid into the cellular tissue after Cantani's method (hypodermoclysis) of treating Asiatic cholera. Injection of several ounces of a weak saline solution every hour or two have proved of great benefit in the latter disease. This, the reader of the paper contended, would be a more judicious treatment of arsenic poisoning than that usually resorted to. After referring to the most probable mode

of action of arsenic in certain diseases of the skin, Dr. Stewart gave an account of a case of acute erythema multiforme following the use of a few doses of Fowler's solution. The intensely reddened skin was covered with innumerable very small papules; there was œdematous infiltration of the subcutaneous tissue of both arms. In another case under treatment with arsenic for angina pectoris, on several occasions an intense temporary erythema of the face had been noticed, and in the same case wart-like excrescences on the backs and palms of the hands which disappeared and reappeared as the arsenic had been stopped or retaken. In both forms of rash there was desquamation, the difference being that in one case it was superficial, in the other deep.

An instance was also recorded of one of the rarest of the untoward effects that follow the administration of arsenic, viz., brown staining of the skin. The case was one of epilepsy in a young man. Bromide of potassium caused such a disfiguring acne that each dose was combined with five minims of Fowler's solution. A few weeks after taking the mixture patient was seen and it was found that the entire body was stained, exposed parts especially so. The staining was not unlike that seen in Addison's disease. It disappeared entirely a few weeks after stopping the arsenic. So far as is known, arsenical staining is not permanent, being different in this respect from silver staining.

Dr. Bell stated that whilst house-surgeon in the General Hospital he had seen not a few cases of poisoning from Paris green, and, as far as he could recollect, there were inflammatory lesions in all cases. He was surprised to hear from Dr. Stewart that in none of his cases these conditions existed.

Dr. Reed said that he had seen one case of arsenical poisoning where there was no gastro-enteritis.

Dr. Shepherd said that if Dr. Stewart's statement was accepted, viz., "that arsenic did not kill by the violence of the inflammatory action excited, but by lowered blood-pressure," then we must altogether change our method of treatment in these cases. The point was a new one to him and he thought the general impression existed that death is in all cases due to inflammatory action. He still had confidence in the use of arsenic in certain diseases of the skin, namely, psoriasis and bullous eruptions, and had, in these cases, used it extensively, but had never seen the erythema or staining produced, but this was probably due to the fact that ointments were used at the same time and in psoriasis especially it would be impossible to detect erythema or staining where chrysophanic ointment was employed.

NEWS ITEMS.

The Medical Corps of the Navy. — Surgeon-General Gunnell and other officers of the medical corps of the navy stationed at Washington are confident that legislation will be secured this year looking to the increasing of the inducements to enter their corps. The Surgeon-General has been before the House Naval Committee, upon the invitation of its Chairman, in the interest of a bill prepared by himself, which medical officers think amply provides for the needs of their corps. The chief aim of the Surgeon-General is to make the rank of assistant surgeon in the navy as attractive as that grade in the army to young physicians. In his statement before the committee he remarked that the corps had not been filled since the war. The number of resignations since that time exceeded one-half the number of medical officers allowed by law. Vacancies are difficult to fill, he stated; the applicants are few, and therefore it is seldom that a young physician is found who is qualified to serve as a medical officer of the navy. A vacancy in the army, the Surgeon-General said, is sought after by hundreds, and no trouble whatever is experienced in procuring physicians thoroughly well qualified to practise their profession.

The success of the army in recruiting its medical corps with desirable men, the Surgeon-General informed the committee, is due to the advantages offered young men who enter the service. They receive a fair compensation and are provided with quarters, and this, together with other allowances, makes their positions well worth seeking. On the other hand, the Surgeon-General stated, the young assistant surgeon in the navy is poorly paid. On board ship he has a hammock in the steerage, where there is no place to study or even to keep his books. It was remarked that the ensigns and assistant engineers are also quartered in the steerage. To this the Surgeon-General replied that those young officers had grown up together and, being jolly young fellows, got along very well. The physician, green so far as affairs pertaining to ship life are concerned, is made the butt for all their gibes and jokes. This disgusts the new man and he soon determines to leave the service which he finds possesses no charms for him, and, in fact, no opportunity to improve in his profession. Besides, he sees staring him in the face an examination of extreme difficulty at the close of the three years without any facilities to prepare himself for it. Five of these young men have left the navy since 1879 and entered the army. The Surgeon-General said that he thought an addition of $200 per annum to the pay of assistant surgeons, with quarters in the wardroom, would enable him to secure men who would be creditable to the corps. He concluded his remarks on the bill by stating that in his opinion the improvement of the medical corps of the navy is a matter that every officer in the navy should be interested in. It is certainly a benefit to the officers and crew of a vessel to have on board a physician in whose skill they all have confidence.

The Epidemic of Typhoid Fever in the Michigan State Prison. — The epidemic of typhoid fever at Jackson, Michigan, in the State Prison, has about exhausted itself, now that the gates through which the germs were introduced into the prison have been closed. A personal inspection of the prison last week satisfied the writer that Warden Hatch has done all that is necessary to do in order to correct the insanitary features connected with the house drainage. The soil pipe from the hospital and its house drain have been relaid so that they can be readily inspected its whole length, and it has been disconnected from the sewer into which the sewage from the west wing enters. An examination of the old conditions shows that the discharges from the hospital water closets had a sheer fall of from 70 to 80 feet, and then entered the sewer with a great velocity, probably siphoning the two traps under a slop sink in the West ward, where most of the fever developed. Under the new

arrangement it will not be likely that the traps will be siphoned. At any rate, the fever has ceased to develop since the warden has carried out his improvements. In the hospital are several convalescents. There were in all about sixty cases, with but four deaths. Dr. Victor G. Vaughan, Director of the Laboratory of Hygiene at the University of Michigan, thus describes how he detected the germs of typhoid fever in the air taken from the sewer: "A quart bottle was filled with boiling water. This destroyed any germs that might be present in the bottle. After cooling, the bottle was held in the sewer with one hand, the space about the arm being closed in order to prevent the gas from coming up into the face. With the thumb and finger the cork was removed from the bottle. Of course the water passed out and the sewer-gas passed in. The stopper was replaced while the bottle was still in the sewer. Some days later a half-ounce of sterilized water was poured into the bottle, shaken, and cultures made with this showed the presence of the typhoid bacillus."—*Sanitary News*, March 3, 1888.

The Cancer Bacillus.—The discovery of the cancer bacillus threatens to have as many claimants as the authorship of Junius's Letters. In addition to Dr. Scheuerlen, who was the first before the public, two Italians announce themselves as having independently made the discovery—Dr. Barnabei, Professor of Clinical Medicine at Siena, and Dr. Sanarelli, a graduate and teacher of the same school. But, it seems, a compatriot of Scheuerlen is also in the field to claim priority in the discovery—Dr. Schill. France, too, not to be outdone, has her special claimant in Dr. Perin. And, finally, Brazil, in Dr. Domingos Freire, seeks to vindicate the honor of the discovery to the New World.—*Lancet.*

A Ptomaine Resembling Strychnine.—Amthor and others have repeatedly found in examining animal remains a ptomaine having many reactions strikingly similar to those of strychnine. It gives precipitates with potassium ferricyanide, chromate, and sulphocyanate, and with picric acid, differing from the strychnine precipitates in that they are amorphous. It gives color reactions similar to those so characteristic of strychnine. Points of difference are its comparative want of bitterness, its very sparing solubility in ether, in washing out from an alkaline solution (its proper solvent being amylic alcohol) and especially absence of tetanizing action on frogs.—*Pharmaceutical Era*, March, 1888.

Dr. Bramann.—The *Lancet* gives the following account of Dr. Bramann, who operated upon the Crown Prince:

Dr. Fritz Bramann has been gazetted in Berlin as the recipient of the Commander's Cross of the Hohenzollern House Order, bestowed by the Emperor as a reward for his skilful performance of the operation of tracheotomy on the Crown Prince. Dr. Bramann is the eldest son of a still surviving landed proprietor near Darkemen in East Prussia. He studied medicine at Königsberg, and acted as assistant to Dr. Schildner, Professor of Clinical Surgery in that school. In this capacity he earned a high reputation for skill as an operator, and was specially deputed from Berlin, where his merits have long been known, to perform tracheotomy, if occasion arose, on his Imperial Highness. Dr. Bramann, who is only in his thirty-fifth year, has had to struggle with many severe illnesses, which wellnigh wrecked his professional career. He has suffered successively from typhus, from enteric fever, and from diphtheria, and on each occasion his life was despaired of by the skilled physicians who were consulted.

Pasteur's Extermination of Rabbits.—The *Lancet* announces that M. Pasteur having entered the lists as a competitor for the reward of £25,000 offered by the Government of New South Wales for exterminating the superabundant rabbits, is sending by the Orient Line mail steamer "Cuzco," three delegates with a supply of "microbes du choléra des poules," with which he hopes to win the prize.

The Dangers of Laundry Work.—Washerwomen are exposed to some undoubted risks in the manipulation of soiled and often infected clothes, etc., and they are generally the first to suffer when an epidemic of any contagious disease breaks out. Even with hands free from abrasions, or other solution of continuity, such diseases may be contracted, but if, as is more often the case, the skin be chapped and raw, blood poisoning, or severe local inflammation, such as whitlow, is extremely likely to follow. The case was reported last week of a woman who died from gangrene, resulting from a finger poisoned in washing the clothes of a person who had succumbed to an attack of phlegmonous erysipelas. The chlorinated solutions used at laundries for bleaching purposes are excellent disinfectants, but they are, as a rule, only used after the washing proper has been done. In this case, a civil action for damages will probably follow, on the part of the children of the deceased woman.—*Medical Press*, February 22, 1888.

Saccharin an Acid.—Saccharin has the properties of an acid. Its compound with cocaine has been prepared, and proves to be a salt freely soluble in water, and having an agreeable, sweet, fruity taste. The compound contains 62.345 + per cent. of cocaine. Combinations with other alkaloids will be produced and their properties studied.—*Pharmaceutical Era*, March, 1888.

The Progress of Cremation.—There are twenty-two crematories in Europe, of which ten have been built within the past year. There have been 600 incinerations in Germany and 800 in Italy. There are seven crematories in the United States, and six in process of construction.

An Important Incompatibility.—The death of a child was caused not long since by ignorance on the part of a physician of the fact that chlorate of potassium and iodide of iron are incompatible. The reaction between these compounds precipitates the iron in the form of sesquioxide, setting free the whole of the iodine, according to the equation $2FeI_2 + KClO_3 = Fe_2O_3 + KCl + 2I_2$. This incompatibility has been pointed out repeatedly, but is not always borne in mind by the physician or the dispenser.—*Pharmaceutical Era*, March, 1888.

Automatic Pill Vending.—An American manufacturer of sugar-coated pills added to the attractions of an exhibit of his product in London an ingenious piece of mechanism, which might have been intended to represent the pharmacist of the future. It was in the form of a cabinet

provided with a series of knobs or buttons, each inscribed with the name of some malady for which a remedy might be asked. The customer puts a coin into a slit and presses the button calling for the remedy he requires, when immediately a drawer flies out containing the article sought. This automatic dispenser, of course, makes no mistakes. If the customer accidentally presses the wrong button, he alone is responsible for the error. Is this really what we are coming to?—*Pharmaceutical Era*, March, 1888.

The Dangers of Medical Missionaries.—Missionaries have usually found that an acquaintance with medicine, and the ability to perform what to natives are most marvellous cures by means of operations, are certain passports in countries where a mere teacher of religion would be in constant danger of being murdered. The lives of Livingstone and many other medical missionaries are examples of this. Even in China, where superstition and hatred of foreigners are at a very high level, medical missionaries have managed to win their way to the confidence of the people in a most remarkable manner. At times, however, there are outburts of fanaticism, promoted probably by the native medicine men, who, in all countries are the most virulent opponents of the introduction of European science. One of these has lately occurred in Foochow. Its immediate cause was the prompt action of one of the medical staff in a case of hemorrhage, in disregard of the native superstition, according to which he ought to have delayed until the patient's friends had finished consulting the gods in the joss-house. As it was, he was unfortunately too late to save the man's life. The enraged Chinamen dogged him from place to place, determined to boil him to death in oil, and had it not been for the courage of some of the converts this would probably have been his fate. As there is a great tendency to wait until the patient is almost moribund before applying for the help of the foreign doctors, it is not surprising that operations frequently fail. It is terrible to think that an unsuccessful operation may result in the murder of the operator. There are, however, signs that China is moving, and the time is probably not very far distant when those who have devoted their lives to the elevation, physical, mental, and spiritual, of the superstitious Chinese will see some fruit of their self-denying labors.—*Lancet*, February 25, 1888.

Duelling Among Medical Students.—A correspondent of the *British Medical Journal* of February 25, 1888, writes from Switzerland that the absurd and barbarous custom of duelling, which still survives with astonishing pertinacity amongst German students from one generation to another, has recently given rise to two sad accidents in Berne. One of the combatants had the whole of his nose slashed off, while another, who was on the point of taking his M.D. degree, had his right arm so entirely disabled by a foil that his medical career has come to a premature end. These accidents, however, did not prevent another series of duels, which took place on February 4th (that is—a couple of days after the above mentioned accidents), in Berne, between several members of the Corporation Helvetia, and as many students from the University of Zurich, who had come to Berne expressly for the purpose. We learn from the *Berner Stadtblatt* of February 7, 1888, that this time no noses were lost and no limbs were maimed, though a good many flesh wounds were inflicted. The police, acting on "information they had received," succeeded in surprising one set of combatants in the morning, and in confiscating the weapons and other fighting gear. This did not, however, cool the ardor of these noble "sportsmen," who managed to bring off some exciting "events" at another place the same afternoon.

The Douche as Affecting Blood Pressure.—Dr. Sergius Vishegorodski, a Russian regimental surgeon, publishes as a graduation thesis some researches on the effects of the general douche at different temperatures on the blood pressure, pulse, respiration, and temperature. The experiments were conducted in the Krasnoselski military hospital, the eleven subjects being feldsher students (hospital orderlies). The reservoir from which the water for the douches was supplied was about fifteen feet above the floor of the bath-room. From the reservoir two tubes, each about three-quarters of an inch in diameter, conveyed the water to the vicinity of the subject; one of these delivered the water in the form of rain; the other delivered three jets directed to the liver, the spleen, and the back. The duration of the douche was two minutes. The blood-pressure was estimated by means of Basch's sphygmomanometer, an instrument which consists of an elastic pad filled with liquid placed over the radial artery, and communicating with a mercurial or aneroid manometer. Dr. Vishegorodski found that with douches of from 63° to 90° F. the blood-pressure was considerably increased, but that douches of from 100° to 114° F. diminished it. The increase of pressure in the former case was found to persist for some time, not returning to its normal amount for more than an hour after the douche. The variations in the blood-pressure occurred simultaneously with corresponding variations in the cardiac beats, the latter becoming slower as the blood-pressure increased and more rapid as it diminished. This appears to be contrary to the results obtained by Delmas, who, however, judged of the pressure merely by sphygmographic observations. Douches of a little over 90° F. produced scarcely any effect on the blood-pressure, the pulse, or the respiration. It is interesting to observe that, in discussing physiological questions, Dr. Vishegorodski—like, indeed, many other Russian writers—quotes as his authority Foster's well-known text-book (Russian translation).—*Lancet*, February 25, 1888.

A Successful Closet.—Architect Stine describes, in the *Sanitary News* of February 25, 1888, a successful closet as follows:

A successful closet must be nearly automatic in its action; it should have no hidden chambers in direct connection with the bowl, that are liable to collect particles of filth which may in time generate foul and dangerous gases to be thrown off into the room. It should be so constructed that no possible back pressure can be exerted from the sewer that would be likely to deprive the traps of their water seal. In other words the soil-pipe should be open to the outer air at both ends. A constant circulation of out-door air can thus be maintained at all times. This method of connections should apply to every fixture in the house. The present custom of boldly exposing every pipe, trap, and bowl to full

view, is one step far in advance of the old method of closing everything in the neatest of woodwork so that none of the piping was visible, and after the work was finished no one knew what was behind it. It was at once a receptacle for dirt, and often the dried results of an overflow of filthy water, and a general cloak for carelessness and neglect, and in time became a veritable pest spot, and disease followed. The physician points to the plumber. An expert is called in, an investigation takes place, and a woful state of things discovered. Possibly no traps under any of the fixtures, and if they are there, they are so connected as to be deprived of their water-seal through siphonage, three-fourths of the time, or so bunglingly put in as to provide an avenue rather than a preventive.

Nervous Shock Produced by Earthquakes.—Many persons who experienced the earthquake in the Riviera have since suffered seriously from nervous shock, although they did not at the time appear to be greatly disturbed. This indicates that more injury may be done to the nerves by an undue excitement than is perceived at the time. The nerve-centres may, as an English medical journal suggests, be likened to batteries, and regarded as apt to be discharged suddenly and sometimes unconsciously; and when once their residual stock of energy is consumed, it can be restored only after a long time and by the exercise of extreme care. It is practically observable that when nutrition is impaired in a nerve-centre or branch, extreme difficulty is met in restoring the integrity of the nervous function, and even the wear and tear of ordinary life seems to increase the exhaustion instead of reducing it by stimulation of the recuperative faculty.—*Popular Science Monthly*, March, 1888.

The Ascaris Lumbricoides in Hens.—ASHMUN writes to *Science* of February 24, 1888, from Cleveland, Ohio, relating the following suggestive incident:

On February 12, 1888, a lady in this city, on opening the egg of an ordinary hen, observed a worm lying coiled in the albumen or "white" of the egg, near the lesser or pointed end. She placed the egg in a saucer, and the albumen flowed out through the opening in the shell, carrying the worm with it. After exhibiting to friends during the day, it was brought to me, February 12th. Upon examination I find it to be an *Ascaris lumbricoides* about four inches in length; and, with the statement verified, the phenomenon becomes interesting in many ways.

An explanation of this occurrence is made as follows by WRIGHT in the same journal of March 2, 1888:

The nematoid worm sometimes found in the white of the hen's egg is not *Ascaris lumbricoides*, as your correspondent of last week supposes, but a *Heterakis*, generally *H. inflexa*, the normal habitat of which is the fowl's intestine, but which occasionally wanders into the oviduct.

Human Electricity.—A hemianæsthetic hysterical female was shown at a recent meeting of the Société de Biologie, from whom M. Féré could under certain circumstances disengage at the surface of the body luminous tufts, one third of an inch long. The son of this woman, likewise hysterical, presented the same peculiarity. In both the skin was remarkably dry. These phenomena could be easily augmented by provoking sensorial excitations. Such phenomena are known more commonly in certain hot and dry tropical climates.—*Lancet*, Feb. 11, 1888.

In Memory of Milton B. Musser, M.D.—The death of Dr. M. B. Musser having been announced at a recent meeting of the Medical Board of the Philadelphia Hospital, the following minute was adopted:

The Medical Staff of the Philadelphia Hospital have heard with sincere regret of the death of their late colleague, Dr. Milton B. Musser, one of the senior members of the Obstetrical Staff.

Coming from a family of physicians, equipped with a complete medical education, and an early training as a hospital resident, with attractive manners, a pleasing address, he was thoroughly prepared, and peculiarly fitted to undertake the duties of his profession.

With large experience and ripe judgment, enthusiastic in his work, honest in all his professional relations, sympathetic, kind, and gentle, he was a model physician, and this institution, that he has so faithfully served, and the staff of which he was so earnest and trusted a member, have lost an honored, tried, and conscientious officer.

The staff desire hereby to place on record their high appreciation of Dr. Musser's many excellent qualities, and the deep sense of loss which they, in common with the community in which he lived, have sustained by his death.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MARCH 10, 1888.

STONE, E. P., *Assistant Surgeon.*—Detached from the Coast Survey Steamer "Bache," and ordered to Hospital New York for treatment.

KEENEY, JAMES F., *Assistant Surgeon.*—Commissioned 1st of March, 1888

BRUSH, GEORGE R., *Surgeon.*—Ordered to the "Omaha" when the "Pensacola" arrives at Aspinwall.

MEANS, VICTOR C. B., *Passed Assistant Surgeon.*—Ordered to the "Omaha" when the "Pensacola" arrives at Aspinwall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING MARCH 10, 1888.

HUTTON, W. H. H., *Surgeon.*—To proceed to Brunswick, Georgia, on special duty, March 5, 1888. Detailed as President of the Board to select a site for the Gulf Quarantine Station, March 10, 1888.

CARTER, H. R., *Passed Assistant Surgeon.*—Detailed as recorder of the Board to select a site for the Gulf Quarantine Station, March 10, 1888.

WASDIN, EUGENE, *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, March 8, 1888.

BRATTON, W. D., *Assistant Surgeon.*—Ordered to examination for promotion, March 7, 1888.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

AMBULATORY AUTOMATISM.

A Clinical Lecture delivered at the Salpêtrière, Paris, Department of Nervous Diseases.

BY PROF. CHARCOT.

GENTLEMEN: You have before you to-day the patient whom you saw three months ago; his history, a very interesting one, is as follows:

Man, thirty-seven years, porter by occupation. In March, 1887, he leaves his home at 8 A.M., suffering from headache, to carry a parcel to one of his master's customers, living about two miles from his home. He takes a car, and stops exactly before the person's house, and even remarks that the person has her address written on the door, but did not go in. Remark well, gentlemen, this is the beginning of a series of incidents which will present themselves successively. It is a very rare fortune to observe such singular phenomena as those before which you find yourself to-day.

Our patient has found the number of the house where he intends to go, but from this moment his remembrance disappears, he is absolutely in the dark. After having reached the house, the next fact he recollects faintly is that he was about four miles from that last place, where he had no business; the next recollection he has, is that he found himself on a bridge, about two miles away from the last place. Remark, he thinks he found himself there, but he is not certain. This is interesting to note, for the disease we think that man is suffering from, presents as a principal symptom, amnesia. But this amnesia may not be complete, and certain vague remembrances might appear here and there.

From the moment the patient found himself on the bridge he walked continuously, until he awakened four miles from that place, at 10 P.M.; that is, he probably walked fourteen hours. During that time his behavior must have been very correct, or else policemen would have arrested him. He must have had his eyes wide open, or else he again might have been arrested. So, he must have conducted himself as you and I; but he was not the less irresponsible and unconscious; and the only points that he remembers during these fourteen hours are, that he was four miles away from his first place of business, then on a bridge, and finally awakening in another part of the city at 10 P.M., where he found himself exhausted, and his boots all worn. He does not remember having taken breakfast, or having spent any money. After having awakened, he went home quietly, and when he reached his home he found himself covered with dust, but no trace of having fallen. The next day he did not feel overfatigued.

From the 15th of March to the 30th of July he worked steadily. On that day he was ordered to take a parcel to a customer. He took a car, and delivered perfectly well what he was charged to do. He then, being very near the place where the "900 feet Eiffel Tower" is being built, thought he would go and see the works. He remembers to have seen the statue of the tower at that time, but from that moment he is again plunged in the dark. He remained two days and two nights without knowing what he did during that time; he finally threw himself into the river Seine, and awakened at that moment. During his sleep he bought a few cents worth of tobacco and a railroad ticket for a short distance. He only had twenty cents in his pocket before he was thrown into this unconscious state.

So you see, gentlemen, how are you going to know when you have a man walking by the side of you whether he is awake or asleep? If there were many people like him it would not be very reassuring to travel. For this man entered a railroad station, took a ticket for Berry, he deposited his money, took his change, received the ticket, and went into the train. When the train crossed the bridge over the river, he threw himself into the water.

A strange incident is the fact that his watch was at the correct time when he came to himself; he did not forget to wind it during this unconscious state. It is true, the same will occur to us. I often, when I retire, try to wind my watch over again, forgetting that I have already done it; he must have done it in a mechanical and unconscious way.

On August 23d he has another attack, he leaves his business house in the morning and goes to all the places he has to, except one. On his way he meets a friend, who asks him whether he could indicate to him a workman. He says he knows one, goes to that workman, and tells him to go to the said place. He then forgets to go home to breakfast; it is 11.30 A.M., his unconscious state begins.

He remembers only on the second day to have passed at Clays, which is twenty-one miles from Paris; he there enters a restaurant and orders a beefsteak, which he does not eat; but he does not know why he did not eat it. He remembers having paid twenty-five cents, but forgets whether he drank his coffee or not; on awakening he found he had put the sugar in his pocket. Then he becomes unconscious again, and he is awakened sleeping under a bridge nine miles from the preceding place. He himself is unable to say whether he slept or not. An amateur fisherman seeing him sitting on the border of the river, and looking steadily toward the river, asked him, "What are you doing here?" "I am looking." "At what?" "Well, I am looking at the Seine." After these questions, he asked the intruder what time it was, his watch having stopped, thanked him, took a car, and came back home.

You will not find, gentlemen, many histories similar to this one. We find here a pathological phenomenon which deserves to be discussed.

I have often asked myself what this singular state of

unconsciousness could be, which would occasionally strike this person for hours, or even days. If we could prevent this man from going about cities without any object in view, it would be a great comfort to him. I have thought, and will try to justify it, that the affection from which he suffers is of epileptic origin; it is the ambulatory form of automatism, an expression which I use to characterize this situation of walking automatically, without any external appearance indicating this automatism.

Remark, that we know very well in epilepsy the post-epileptic insanity. An individual has an epileptic fit, and, under the influence of terrible dreams, he becomes violent, he breaks everything, and he begins to walk; but he is soon arrested, and finds himself at the police station.

Those epileptics might murder some one, commit suicide, while our patient, if he had not been able to swim, would probably not have thrown himself into water. In this there are no traces of over-excitation or violence. In a general way, on the contrary, the terrible violence of the fits is one of the characters of post-epileptic mania; it is probable that we have not these conditions in this case, but they are probably the same series of phenomena under a different aspect. You know that in epileptic fits we distinguish the grand mal and the petit mal.

The words "petit mal" seem to indicate a lesser degree in this affection than grand mal. This is a false idea. It is only apparently a lesser affection, in reality it is not. It has the same consequences that the grand mal has, and sometimes it is even more grave, in a prognostic point of view. Generally we divide it into degrees. The individual who speaks with you suddenly becomes pale, his speech stops, he becomes unconscious for a moment only. If he has anything in his hands he might let it fall, after a few moments his consciousness is restored, this is what we call absent minded. After this comes the vertigo. The patient has the sensation of something turning around him, or that he is himself turning. There may be, in addition, certain movements in the lips which represent convulsive attacks, which are the initial characteristic of the epileptic attack. One employs wrongly the term vertigo to express the state of certain patients who become unconscious without having the vertigo sensation, but who have few convulsive movements.

These attacks of petit mal, I have said for a long time, are as serious in character as the grand mal, in which the patient bites his tongue, the consequences are as serious in regard to the psychical phenomena. One often sees, after an attack of petit mal, the patient rise, make a few steps—speak out single words, always the same during the fit. I knew one, who, on every attack, would continuously say, thirteen, fourteen, fifteen, then begin to walk, in an apparently normal condition. A minute later, all was over. This is the germ of the ambulatory fit. Prolong this state in your mind, and you shall have the picture of the history which this patient has given us, admitting my diagnosis to be correct.

You will find many descriptions of this phenomenon in different works. It is called automatism, and if you want to read something interesting in this respect, I recommend you the paper of Mr. Jackson, of London, on the subject of ambulatory automatic fits, not accompanied by emotions, anger, or violence, and which have such an analogy to the phenomenon of natural somnambulism, that it is questionable whether any difference in the symptoms can be established between these two groups of natural somnambulism and comitial somnambulism.

You often have heard said that epileptics after their fit will behave in a scandalous manner. One will undress himself entirely, as did a professor of music, who, after having given a lesson, to a young lady, suddenly takes off his clothes.

Jackson also reports the case of a man who goes to a restaurant, eats and conducts himself perfectly. He pays, comes home, but does not remember he has gone to the restaurant, and has no sensation of hunger. This case is mentioned as remarkable. Our case has remained two days unconscious. These cases are exactly similar, except that in Jackson's case unconsciousness lasted three or four hours, while in ours the patient remained two or three full days absent minded, behaved very well during that time, which prevented him from falling into the hands of the police.

I have thought it was a case of comitial automatism, but you will say, Are you certain it is not a particular case of somnambulism? I have admitted the comitial point of view, for if it is so, we can treat him. When I saw him for the first time some months ago, he had just had his third attack; we have since given him a preparation containing bromide of potassium.

The first week we gave him 60 grains a day; the second week, 75 grains; the third, 90 grains; the fourth, 105 grains a day. The same treatment the following month. Then he had a fourth slight fit.

One morning he had headache in the left temporal region, and was delivering his goods; while sitting at the side of the coachman he begins to sleep, his companion awakens him. He delivers a parcel, but forgets how he did it. He returns to his business house, and his employer remarks a strange look about his eyes, he is unconscious while speaking to him. He has his eyes wide open. You know that in Macbeth, there is a very deep observation of somnambulism. The physician who is present, seeing Lady Macbeth rise and begin her somnambulic acts, addresses himself to the other persons on the stage, and cries out, "See, her eyes are open!" This is the great question to know, whether the eyes are opened or closed in somnambulism. Our man must have had his eyes open, for he spoke to his employer and also took a railroad ticket.

After having seen his employer, he again, with the same coachman, goes to another place, and complains to his companion of being very tired and very thirsty. When he returned home, he drank a great deal of water, and felt all over his body as if he had been beaten This attack lasted only three hours. After his fits he will sometimes recollect facts which have produced themselves during his unconscious state.

In cases of epileptic fits with violence, we generally say that patients have absolutely forgotten what they have done. This is usually the rule, but there are contrary examples. I remember a case in which a man, after an epileptic fit, had broken everything in his house. The wife and everybody else had run away. He then went out of the house, out of the city into the country, where he shortly awakened, forgetting all that had occurred. He then returned home, and found everything broken, and was greatly surprised to hear that he did the

mischief. He told me afterward that he now thought he had dreamed he had broken everything in his house. You note here, the remembrance of the accomplished act in presence of the results. It is certainly a phenomenon of the same order which makes this man before you to-day remember that he ordered a beefsteak which he did not eat. All this remains in the mind, as a dream, without the memory of the accomplished acts.

But you will say, Is it epileptic; is it not natural somnambulism? There are clinical differences, but there is a resemblance in the form.

Natural somnambulism, as it is called in opposition to artificial somnambulism produced by hypnotism, is a disease of youth and first childhood. It is rare to see it manifest itself in adults or old age. The somnambulistic acts also take place at night, and ordinarily we do not observe the patients at that time, so we have to rely on what parents will tell us about it.

A few minutes ago I was mentioning a passage of Shakespeare, who has shown himself to be a very deep observer in medical subjects as in many other questions. He has given the same definition of natural somnambulism as Joseph Franck. This meeting of the poet and medical man is a curious one.

Shakespeare says, in Macbeth, to define the state of Lady Macbeth:

"A great perturbation in nature! to receive at once the benefit of sleep, and do the effects of watching."

What does Joseph Frank, the physician, say?

"Somnambulism is a perturbation of nature in which the patient has all the appearances of sleep, and yet does all the acts which are done when awake."

If I should wish to define the mental state of our patient, I would say it is that of an individual who appears to sleep, but who behaves as you and I conduct ourselves while awake. He has certainly some strange ideas – to throw himself into the river, for example; but he nevertheless seems to act with reason, and yet he sleeps; his consciousness sleeps; and when his normal life returns he forgets what has occurred during his sleep. We have here a case of somnambulism, or noctambulism, if you prefer. One of the characters of somnambulism is to be nocturnal. Usually somnambulism will nearly always manifest itself at the same hour, midnight, or 1 A.M. So there are children seen to walk in their room, accomplish certain acts, study their lessons for school, etc. I have never heard of a diurnal (daytime) somnambulism, and should I hear of it, my first thought would be that it was a case of comitial somnambulism.

We have here a patient whom you already know, and who presents all the symptoms of natural somnambulism. She is an hystero-epileptic; but I say she is a natural somnambulist with a certain doubt. This patient rises at 2 A. M.

The following are the principal incidents of her somnambulistic life, and the circumstances which make me doubt whether it is natural somnambulism, or whether she is not epileptic. The case was a very interesting one for me to study, for while we have here a service of two hundred epileptics, I had never for the last thirty years I have been connected with this hospital, heard of a case of natural somnambulism present in this house.

My students decided to pass the night to watch her. They saw her rise, and followed her in all her doings, until she returned to bed again. They have made some very interesting observations, so much the more so because it is a difficult matter to get an accurate description of these cases. They saw her leave her bed, jump out of the window, which was nearly on a level with the ground, pull a little working carriage which was in the yard, try to go out by the back door of the hospital, finding it closed, she went up on a wall, and began to run on it without falling.

Another night, the door having been left open purposely, she walked out into the garden and cut some dry stems of plants, of which she made a bouquet, which she took back to her ward, went to bed again, with her eyes *open*.

Shakespeare, in a *Macbeth* scene, says: "Her eyes are open." It is a very interesting observation, coming from a writer who is not a medical man; one might think he intended giving to the nosologists a lesson in pathology. He observed one of the principal symptoms of somnambulism, after having given a definition exactly similar to the one of Franck.

I have asked myself whether in natural somnambulism there are no somatic contractures, and whether there exist any difference in this respect between natural and artificial somnambulism. We have found none of these contractures in our female patient, who can be placed in a state of artificial somnambulism with contractures.

The somnambulist patient has his dream, his idea, he will do it, and will omit all which is not in his programme. If you place yourself before a patient in somnambulism, he will pass on the right or left side of you, not paying any attention to you, who are not present in his dream. It is said that Stuart Mill, while thinking of some philosophical subject, would often forget himself in the streets of London, not seeing the persons going by, absolutely a stranger to the outside world, and yet walking in a very natural manner; during that time he belonged absolutely to his mental education. It is a singular faculty not to see what does not interest you. And yet, if we examine ourselves, we find that not one of us has not gone up a stairs, arrived at a door, opened it, thinking of an entirely different subject. So it has been from the time of Hippocrates down to our days, we do not see our diseases, we are unable to see them. All the physicians have walked in the midst of locomotor ataxia down to the end of this century without seeing it; they have not seen multiple sclerosis; five years ago, I saw for the first time the hystero-traumatic paralysis.

I am not certain that in our patient we have to deal with natural somnambulism, because our patient is an hystero-epileptic with separate crises. In general, we never find epilepsy in our somnambulistic patients, but oftener hysteria.

To come back to the patient before you, to justify the diagnosis in these cases is always a difficult matter, on account of our superficial knowledge of the disease.

There is no case of epilepsy, whatever its form, which does not justify at least the temporary use of bromide of potassium; and if the patient is not cured, we at least find a beneficial influence of the drug. It would be important to know whether in this patient there is anything comitial which has any relation with the ordinary type.

The history of his family is a good one; no traces of nervous disturbance can be found. When a child he always felt perfectly well, has had no convulsions, nor indications of any nervous disorders.

A few minutes ago, I was speaking to you of psychological equivalents to the convulsive attacks. In general they are post-epileptic accidents which follow a fit of epilepsy, or vertigo, or an absence of mind. Sometimes the fit can be suppressed, and yet the ambulatory act can be produced. It would be a case of this kind, in presence of which we find ourselves to-day. I am not certain, however, that there is not here a slight vertigo.

I know an architect who consults me very often. He has frequent absences of mind. He enters a car desiring to go to a certain place. He will pass that place and awakens when the car arrives at its final station. These are post-comitial phenomena.

In regard to our man, I think after all the considerations I have unfolded to you, that we have to deal with a particularly remarkable case of comitial disease, or ambulatory automatism. It is the first time that I have seen an affection of this kind with such clearly pronounced symptoms, you will find no more interesting ones in your nosological descriptions. This man will continue his treatment, as he has done up to now. He will take 75 grains of bromide a day for a week, then 90 grains for a week, the 105 grains the third week, and then over again; and he will report in three months from to-day.

ORIGINAL ARTICLES.

AMBLYOPIA BRIGHTII VERSUS RETINITIS ALBUMINURICA.

By D. C. COCKS, M.D.,
SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

The recent paper by Dr. Pooley, of New York, read before the New York Academy of Medicine January 19, 1888, revives a subject that although a permanent part of the literature of medicine, yet is so seldom referred to that its existence is often forgotten. I refer to the fact that failure and even complete loss of sight may occur in Bright's disease without any changes in the retina or choroid.

Every third course student has heard of neuro-retinitis albuminurica, but the writers of some of our text-books have forgotten to mention that there is an amblyopia Brightii unattended by lesions of the fundus oculi. In view of these facts I have thought proper to refer to a few cases that have occurred in my practice illustrating this particular symptom of Bright's disease, and by way of contrast will give the history of a case of retinitis albuminurica, hoping thus more forcibly to impress the fact of the existence of amblyopia Brightii without ocular lesions.

CASES OF URÆMIC AMBLYOPIA WITHOUT OCULAR LESION.

Case I.—A few years ago I was called to see a youth about twelve or thirteen years of age, who had been seized with convulsions of an epileptic character and due as I afterward found, by an examination of his urine, to acute Bright's disease. He had been sick for several days, had had nausea, headache, vomiting, and scanty urine, followed by the convulsion for which I was called. When I arrived he had partially aroused from the stupor which always follows these attacks and was complaining that he could not see. The following day I made a careful ophthalmoscopic examination: his sight was entirely gone, he could not even perceive the light thrown by the mirror of the ophthalmoscope. The pupils were dilated widely, but the fundus of each eye was normal. On the closest examination, as this was my first case, I could not find any organic lesion in the retina, choroid, or nerve. This state of eyesight continued for about thirty-six hours, then perception of light was noticed, then objects indistinctly, and finally *perfect* sight was restored. I saw him quite a while afterward, but there had been no further trouble with his eyesight, and his kidneys had returned to their normal condition.

Case II.—Mrs. M., aged forty-five, having previously enjoyed good health, was suddenly taken with intense headache, then failure of vision, slight delirium, complete loss of sight, and finally unconsciousness. Examination of the fundus oculi was negative, the urine showed abundance of albumen. She seemed to recover entirely from this attack, both as to sight and kidneys. One year after this she had a similar attack, not so severe however, and with a like happy termination. The duration of the amblyopic symptoms was about ten days.

Case III.—Mrs. C., aged twenty years, pregnant for the first time (seven months), noticed slight œdema of her feet August 31, 1884; this increased, and her physician, Dr. Lyon, found her urine loaded with albumen. Uræmic convulsions having developed she was delivered by Dr. McLean while she was unconscious (uræmic coma). The following day she partially aroused from this unconscious state, and it was found that she was partially blind, being able only to discern large objects. I made an ophthalmoscopic examination and found no changes in the fundus, except possibly a slight œdema of the retina near the nerve. Three weeks after this her sight was perfect. She also recovered entirely from her nephritis.

CASES OF RETINITIS ALBUMINURICA.

Case IV.—Miss D., German, aged twenty-five, always supposed herself to be in perfect health until January, 1885, when after exposure to wet and cold she noticed that her urine was scanty and high colored. Six months from that time she was seized with severe and constant headache, chiefly occipital, attacks of dyspnœa, œdema of the feet, and slight blurring of sight. These symptoms led to a careful investigation, when it was found that she had chronic Bright's disease, hypertrophied heart, and neuro-retinitis albuminurica. The eyes externally looked normal, the pupils were equal in size and responded readily to light; V. $= \frac{20}{XX}$. At times, however, she said that things looked hazy. The media—*i. e.*, aqueous, lens, and vitreous—were as transparent as in health.

The optic nerve was slightly swollen, its edges

were blurred, the retina had an indistinct look as if I was examining it through a thin veil, but the most striking appearances were two groups of white spots scattered over the fundus. The first group was to the temporal and upper side of the optic nerve, covering a space the size of the optic papilla; the second was grouped about the macula in a crescentic arrangement, looking as if spattered into it by a paint brush, the veins were slightly enlarged, but there were no marked changes in the arteries. This description answered well for both eyes.

From this examination a diagnosis of neuro-retinitis albuminurica was made. It was the second stage of the disease, and so characteristic was it that, taken with the persistent headache, swollen feet, and hypertrophied heart, morbus Brightii could have been predicted without a urinary examination being made. I do not mean to state that the changes in the retina were pathognomonic, because a few cases have been observed where this condition existed without kidney disease having been proved present, but I do mean that, when seen, the kidneys should be at once investigated; but when this appearance is accompanied by the group of symptoms named—*i.e.*, persistent headache, nausea, œdema of the hands and feet, hypertrophy of the heart—a diagnosis of chronic Bright's disease can almost positively be made, irrespective of a urinary examination.

These appearances once clearly seen even by the tyro in the use of the ophthalmoscope, would leave him not faultless if, seen a second time, they did not suggest an examination of the kidneys. In the first and last stages of albuminuric retinitis, the picture is not so distinctive or suggestive. In the first stage all that can be noticed is a fulness of the retinal veins, an increased redness of the nerve, which soon passes over into a decided neuro-retinitis (in a case now, February, 1888, under observation, there are a few feathery retinal hemorrhages, with no swelling of the nerve), the veins becoming larger, more turgid, the edges of the nerve are lost to view in the œdematous swelling of the connective tissue of the head of the nerve, and by the development of new bloodvessels. The retina is noticed to be dotted with minute white spots, both in the neighborhood of the nerve and the macula.

If the disease continues to progress beyond this point, these spots increase in size, and coalesce, covering the retinal vessels in their neighborhood, and thus form a uniform mass of exudation. At this stage, and even before, hemorrhages make their appearance; if these are small, they are situated in the retina, causing immediate damage to the sight, according as they are situated at or remotely from the macula, and, as a rule, slowly disappear by absorption; if large, they sometimes break through into the vitreous, causing immediate and marked failure of the sight, thus simulating the amblyopia without lesion.

Where the hemorrhages are in the periphery of the retina, their presence may cause no inconvenience to the patient, and may escape the observation of the physician, unless carefully looked for. The nerve may become very much swollen, as in a case now under observation, in which the apex of the nerve can be seen with + 7 D., the macula being emmetropic. If life is sufficiently prolonged, partial atrophy of the optic nerve may result. In favorable cases, as in morbus Brightii from pregnancy or scarlatina, where the patients entirely recover from their kidney trouble, a retrogression of the eye symptoms takes place, and if the nerve has not suffered too much from the swelling, and the hemorrhages have not involved the neighborhood of the macula, complete recovery may take place.

The greatest danger that menaces a patient sick with Bright's disease is uræmia. In other words, the patient is in danger of poisoning by the retention in the system, not of the urea alone, but of all the urinary salts, and of having developed in his body that train of symptoms which has been included under the term uræmia. This danger and these symptoms vary according to the condition of the patient at the time the symptoms are first noticed, and according to that part of the system on which the brunt of the attack falls. If the case is one of acute Bright's disease—in other words, if the patient's system has not been accustomed to the presence of urinary salts, except in the normal amount—a day or two may permit the most serious uræmic phenomena to be developed, the urea in the blood being only a fraction of that to be found in the blood of a patient sick with chronic "Bright's", who seemingly suffers no inconvenience from it. Uræmic symptoms will show themselves, then, in a given case, more or less acutely, according as the system has been accustomed to its presence or not, and according to the suddenness with which its elimination is stopped.

Where and when uræmic symptoms will first manifest themselves it is never possible to say; whether with dyspnœa, vomiting, deafness, amblyopia, delirium, or convulsions; in other words, whether some one nerve centre may be so strongly affected as to lose its function, or the whole brain be at once overwhelmed by the poison.

Uræmic amblyopia is a failure or loss of sight without any observable pathological changes in the optic nerve, retina, choroid, or refractive media of the eye, and is due to the poison of urea and other constituents of the blood acting on the intra-cranial centres of vision. In uræmia the loss of or failure of sight may be the first symptom noticed, and the other symptoms may readily follow, or we may have first the headache and then failure of sight, or we may have convulsions, and loss of sight be first noticed as the patient recovers from the coma. In this last instance the patient's mind may recover

sufficiently to express the fact that blindness exists, and yet memory be in abeyance, and on complete recovery no memory of loss of sight remain.

In regard to the onset of the amblyopia it is generally sudden, a few minutes or hours being sufficient to blot out all perception of light: but it may be first noticed as a fog between the patient and surrounding objects, which gradually deepens until sight is lost. In other cases the sight is often only slightly impaired, and that for a short time. In this particular it differs from diabetic amblyopia, which may be permanent. In regard to the duration of this trouble it can be stated that, as a rule, it develops suddenly, and disappears suddenly, exceptionally it is very slow in its progress. The prognosis is, as a rule, good, the sight being completely restored, and relapses are infrequent. I have no record of any case where vision failed to return if life was prolonged. In this respect it differs from albuminuria retinitis, as in this latter sight is scarcely ever restored.

The diagnosis of this condition is especially important. In all cases of sudden loss of sight where the ophthalmoscope shows no lesion, the urine should be examined both for albumen and sugar. I have no figures, nor have I been able to find any record of the frequency with which uræmic amblyopia appears in Bright's disease, but I believe that if all cases were carefully examined for this symptom, we would find it present in over forty per cent. of all cases, while neuro-retinitis occurs in about thirty per cent.; this last may be monocular or binocular, while I know of no recorded case of monocular amblyopia Brightii.

We have thus in the eye exhibited on a small scale the counterpart of the changes that take place extensively in other parts of the body in Bright's disease. The amblyopia is produced in the same way and by the same poison as that which produces headache, dyspnœa, failure of memory, delirium, and, finally, loss of consciousness and eclampsia; all of which symptoms show after death, no changes to account for their development during life. In the eye we can make ante-mortem examination and find the tissues of the retina and choroid normal.

Neuro-retinitis, on the other hand, is produced in the same manner as pleurisy, pneumonia, pericarditis, and cerebral hemorrhages. It is a part of the changes which take place in the vascular system. These two conditions, while totally distinct, may yet coexist in a given case, so that the failure of sight in commencing neuritis may be out of all proportion to the lesion found in the fundus.

I have redescribed these two symptoms of Bright's disease, not simply as curiosities, but because they are of the greatest importance to each general practitioner, as a failure to recognize the functional trouble, and the consequent erroneous prognosis as to the recovery of sight would react unfavorably on the practitioner: while, if its existence is appreciated, we may calm the fears of anxious friends by stating that if life is prolonged sight will be entirely restored; on the other hand, the albuminuric retinitis has been frequently the first symptom that has disclosed the disease back of it. It stands in many cases written out on the fundus as plain as if letters were there in place of the characteristic splashing produced by the fatty degeneration of the connective tissue of the retina; and here the prognosis as to recovery of sight is most serious, and as Bull and Gruening have so clearly proved, the prognosis as to life is most unfavorable.

Conclusions.—The amblyopia of Bright's disease is totally distinct from the loss of sight in retinitis albuminurica, the one being a functional disturbance of the centres for sight in the brain, the other a lesion of the interior of the eye itself.

That while they are often seen separate and distinct, as in the cases reported, yet that they may coexist in one and the same individual.

Every general practitioner should possess an ophthalmoscope, and thus be able to make a diagnosis himself.

A CASE OF PRENATAL, AND A CASE OF POST-NATAL PNEUMONIA.[1]

By BARTON COOKE HIRST, M.D.,
Demonstrator of Obstetrics in the University of Pennsylvania.

A few months ago I had an opportunity to study the case of a newborn infant that died shortly after birth from a pneumonia contracted *in utero;* quite recently I have seen an infant, apparently healthy and well developed when born, with no inherited disease, exhibit all the symptoms of a catarrhal pneumonia within a few hours after its birth, which proved fatal in the course of three days. The origin of the disease in the two cases, the clinical history of each, and the post-mortem appearance, contrasted so sharply the one with the other, that a brief description of these cases may indicate the distinctive features in an attack of pneumonia which begins and runs its whole course perhaps *in utero*, and one which is first developed immediately after birth.

Case I. *Prenatal Pneumonia* (Philadelphia Hospital).—An Italian woman, æt. thirty-five, at the time of admission pregnant six months, having for a year past suffered from a large lumbar abscess constantly discharging pus, and exhibiting, during the time she was under our observation, all the signs of general septicæmia, gave birth to a living infant between the seventh and eighth months. The child was tolerably well developed for the period of pregnancy, but was deeply cyanosed, and evidently breathed with difficulty for the few hours that it remained alive. The post-mortem examination showed

[1] Reported to the Philadelphia Obstetrical Society.

no other cause of death than the condition of the lungs, which were as large as though they had been well inflated with air, but in their consistency, weight, and color, throughout all the lobes of both lungs, resembled a liver; placed in water, they sank at once. A microscopic examination showed an enormous overgrowth of fibrous elements, and a desquamative pneumonia in the air vesicles, which were compressed and distorted by the encroachment of the overgrown inter-alveolar connective tissue.

This would seem, therefore, to be the first stage of what is known later as "white pneumonia," when the lung substance has undergone fatty degeneration, and presents a peculiar appearance which is usually regarded as symptomatic of congenital syphilis. There may be cases, however, in which, it seems to me, such a condition might be found, although the possibility of syphilis were entirely excluded.

Geyl,[1] by a series of careful experiments, has shown that when the oxygenation of the fœtal blood is interfered with, the fœtus makes inspiratory efforts *in utero*, with the result of drawing into its lungs a large quantity of liquor amnii; and this author has further demonstrated that the presence of liquor amnii within the lungs, containing, as it does, lanugo, epithelial scales, urine salts, and perhaps meconium, is capable of exciting a catarrhal pneumonia.

Now, in any condition that interfered with the aëration of the mother's blood, or if from any cause the fœtal blood could not be properly oxygenated, there might be an attempt at pulmonary respiration on the part of the fœtus, resulting in catarrhal pneumonia, which ultimately, from the constant irritation caused by the desquamated epithelium and the solid particles held in suspension or solution by the liquor amnii, would bring about the overgrowth of connective tissue that characterizes a pneumonia arising *in utero;* this interstitial inflammation of the lungs, therefore, need not invariably be ascribed to syphilis.

Whatever the explanation of its occurrence, the diffuse nature of an inflammation of the lungs during intra-uterine life will usually be sufficient to distinguish the disease from the same affection arising immediately after birth.

Case II. *Post-natal pneumonia* (Maternity Hospital).—A healthy young primipara fell in labor at six o'clock in the morning, a few weeks ago. With the first few pains the membranes ruptured, and the greater part of the liquor amnii escaped. At half-past six in the evening the os was dilated; at ten o'clock the child was born, slightly asphyxiated, but was soon revived. The mother stated from the first that the child breathed rapidly and refused the nipple; by the third day it was evidently quite ill, and its temperature was found to be 101°. My attention being called to the case for the first time, I found fine râles over both lungs, but no distinct dulness. From its history and physical signs, the case was thought to be one of pneumonia, from the inspiration of blood and mucus during labor. The child died upon the following day. In all the lobes of both lungs were found spots of solidification about the size of a chestnut, the remainder of the lung tissue being apparently healthy. The right auricle of the heart was enormously distended; the foramen ovale was almost completely closed.

Perhaps this form of pneumonia occurs more frequently than is commonly supposed after difficult or tedious labors, and it may be that many obscure cases of fatal disease in newborn infants might be explained if the lungs were carefully examined.[1]

[1] Die Ætiologie der sogenannten puerperal Infection des Fötus und des Neugeborenen, Arch. f. Gynäk., 1880, Bd. xv. S. 384.

[1] Henoch, in his interesting book (Vorlesungen über Kinderkrankheiten, S. 338), refers to a "Schluckpneumonie" from the inspiration of milk while feeding, but says nothing in this connection about the inspiration of the discharges of labor. Schröder, however, in his lectures, was in the habit of referring to this subject at some length. Schultze has actually listened to the respiratory efforts of a fœtus in utero, and many others have heard the *vagitus uterinus*.

WHAT IS A HOSPITAL CORPS?

By JOHN VAN RENSSELAER HOFF, A.M., M.D.,
CAPTAIN MEDICAL DEPARTMENT U.S.A.

A quarter of a century of profound peace has largely rendered latent the costly knowledge which war taught us. A generation has grown since Appomattox put an end to our last and greatest conflict, to which its lessons are unknown; and to-day, should war be declared, it would find us almost as unprepared as in 1861.

Considering the fact that the regular army of the United States is but a nucleus around which the greater army of the people must crystallize when any war comes upon us; and accepting one of the axioms of warfare that the average soldier is made, not born, it behooves us to think, whether we have forgotten how to restore our nearly worn-out ploughshares and pruning-hooks to their original shapes. Quite as important is this question to us of the medical profession as to any other class, for the civil practitioner of to-day will, in event of hostilities, become the medical officer of to-morrow. To you, then, medical officers of to-morrow, is addressed this question, What is a hospital corps?

A leading article in The Medical News of Jan. 28, 1888, states that a hospital corps has been organized in the United States army, and gives an excellent *résumé* of its plan and scope, but the fact that such organizations exist, and have existed for years in all the great armies of the world as an acknowledged factor of the utmost importance, is not generally recognized in this country.

The idea that a company, battalion, or larger body of men, marching in review, is complete in itself, and the final development of active service organization, would hardly now be entertained by

the merest tyro in the art of war. Yet such has been the belief amongst other nations, and such ideas doubtless obtain to-day among our own countrymen who have given, if any, only a passing thought to the subject.

The British army went to the Crimea without hospital corps, without field hospitals, with an untrained medical staff, with no systematic base hospital organization. The result, from a medical standpoint, which might have been anticipated, was utter failure, and the horrors of the Crimean winter of 1854–55 furnish the darkest episode in the history of that war. Our own experience in 1861 was identical, and the outcome would have been the same, had not the whole country risen in compassionate effort to supply the deficiencies in our army hospital arrangements. A glance at the records of the early part of the war, as published in *The Medical and Surgical History* thereof, must convince the most sceptical that in no direction were we then less prepared to cope with the immense problem which presented itself, than in the medical department. The conclusion was grand, but who can tell the amount of preventable suffering through which we passed to reach that conclusion?

One of the outcomes of this dearly bought experience was the organization of an ambulance corps, which served an admirable purpose during the latter part of the war, and with its close, except on paper, ceased to exist. But other nations, profiting by our experience, took up the medical war scheme where we left it, and have carried it to the perfection which characterizes army organization in Europe to-day. A marked advance toward this result followed the development of the German system, in which, commencing on the fighting line, the relation between the regimental medical aid (medical officers), the regimental sanitary detachments (soldiers of the line detailed and instructed as stretcher-bearers), the divisional bearer companies (hospital corps soldiers), the field, communication, and base hospitals, and hospital transports (boat or rail), is clearly defined. But it may be asked, Why this elaborate system? Experience has emphasized the fact, that "any military body, trusting for its medical efficiency to the battalion aid alone, must of necessity come to utter grief when the battalions have to move forward off the battle field, and the sick and wounded must look for attention to other hands than those of their regimental comrades." The combatant soldier's sole function is to fight, and the hospital corps soldier's to care for him when he falls.

It is needless to dwell upon the value of such an organization; twenty-five years ago some questioned it, to-day no one who has investigated the subject can doubt that a hospital corps is essential to a properly organized army. Such a corps cannot, however, be recruited and perfected in a week. There must be officers to teach before men can learn, and the object of this paper is to suggest to the profession, very crudely indeed, a convenient method by which a large number of medical men can profitably, and almost without effort, be taught many of the duties pertaining to the medical officer.

The uniformed militia of the various States furnish the foundation upon which the proposed organizations may be based, and the medical schools the material and means of instruction.

It requires two percentum of the fighting strength of an army to take care of the invalids. Upon this basis there might be organized in each State a hospital corps numbering two percentum of total uniformed militia. This corps should be divided into companies containing say three commissioned officers (medical), thirteen non-commissioned, one musician, and forty-eight privates. It should be uniformed and be an integral part of the national guard, subject to the same regulations, entitled to the same privileges, and raised by recruitment, as are all other soldiers of the guard. But, since the duties of the corps are special, and essentially in the line of medical education, the medical students might furnish the material and the medical schools the means of instruction, thereby adding largely to the scope and usefulness of both, and resulting in mutual benefit to students, school, and country. These companies should not, however, be wholly composed of medical students, but a certain proportion should be recruited from among men in other pursuits, who are anxious to familiarize themselves with "first help" methods, etc.

The proposed hospital corps of the National Guard should be uniformed, equipped, instructed, and drilled in like manner as the hospital corps of the regular army, in order to insure entire unanimity of action between organizations which must serve together in the event of hostilities. It should be officered by medical officers of the National Guard who would be responsible for its proper discipline and instruction, and the corps should always be under control of the medical department. Such an organization would correspond to the divisional (stretcher) bearer companies of the German system. It would not only furnish soldiers trained to meet the surgical emergencies of the battlefield, but also men skilled in the manifold duties pertaining to military hospitals, both field and permanent. In a word, it becomes responsible for the invalid from the moment he falls on the fighting line till restored to health, discharged for disability, or buried with military honors.

In addition to the hospital corps composed of soldiers, as already stated, whose sole function is the care of the invalid, there should be detailed four men from each company of the guard, to be known as company stretcher-bearers, who are to be instructed in "first help" methods, and whose duty will be to

assist in removing the wounded from the fighting line, when they are required to supplement the bearer companies. These soldiers belong to the line of the army, and can only be used for bearer purposes in an emergency.

In the United States Army they are detailed by the company commanders, with concurrence of the senior medical officer, are excused from no company duty, and are only under control of the medical officer when in the actual performance of bearer duty. They in no sense belong to the hospital corps, and correspond to the regimental sanitary detachment of the German system.

The course of instruction may be outlined as follows:

1. Infantry drill through the school of the company. It must ever be remembered that the men of the hospital corps are soldiers, identical with the soldier of the line in every respect except as to their special functions, and that their efficiency largely depends upon their discipline. Ordinary drill promotes discipline, as well as lays the foundation upon which are based the stretcher and ambulance tactics. This drill is conducted by medical officers in foreign armies, who are taught to be soldiers as well as surgeons. In our own, the enlisted man is required to serve a year in the line before transfer to the hospital corps.

2. First aid to wounded, embracing elementary anatomy and physiology. Treatment of fractures, dislocations, and sprains (including improvising of splints and dressings).

Arrest of bleeding.

Transport of injured.

Resuscitation of apparently drowned.

Nursing.

Names, use, and care of surgical instruments.

General principles of sanitation.

3. Stretcher drill, the lifting, carrying, and lowering of wounded.

Command of aid parties at accidents, or in the field.

Improvised methods of carrying injured.

Structure and loading of ambulance wagons, and the utilization of ordinary wagons for carrying wounded.

Loading and unloading of mule cacolets and litters.

Loading and unloading of ambulance railroad trains, and the manner of arranging cars for carrying wounded.

Battlefield aid, formation of dressing stations, field hospitals, etc.

Camp kitchens, and cooking.

The general duties of a hospital corps soldier in the field.

4. The proper method of organizing so-called permanent hospitals during active service, discipline, nursing, cooking, water supply, ventilation, washing, dispensing of medicines.

The care of public property, keeping of records, accounts, etc.

Rendering of returns and reports.

Army regulations and orders; particularly those pertaining to the medical department and hospital corps.

It can hardly be denied that great advantage would result to the country as well as to the individual, could there be a general dissemination among medical men of a practical knowledge of all these subjects, which make the army medical officer a specialist, in the broad meaning of that word.

It is quite true that many medical men may not be called upon to use it, but the probabilities are largely in favor of the opposite conclusion. Certainly should war come to us—and come it must—the profession of the country would be largely responsible for its medical results.

Must we then, again, begin "without hospital corps, without field hospitals, with an untrained medical staff, with no systematic base hospital organization?"[1]

Fort Reno, Indian Territory, February, 1888.

MEDICAL PROGRESS.

Three Recent Interesting Cases of Brain Surgery.—At a meeting of the Surgical Section of the Royal Academy of Medicine on Friday last, three successful cases of trephining were reported, and the discussion upon the papers was adjourned to a future night. These cases were all remarkable. Prof. Thornley Stoker read particulars of a case in which a man fell from a cart while drunk. He came to the Richmond Hospital some days later, rather stupid, and with some lightly marked paralytic symptoms. It was not easy to determine whether he had not had an attack of apoplexy. The paralysis becoming more marked, Mr. Stoker trephined in the region of the fissure of Rolando—there was no fracture—and struck the margin of a blood clot. He again trephined and more fully exposed the clot, which was washed out. The area so compressed was about three inches, and the clot measured nearly an inch in depth. The patient recovered and was exhibited. Sir W. Stokes read a paper on a case of successful trephining for cerebral abscess, and exhibited his patient. The man had been struck with a poker on the left side of the mesial line of the head, and about an inch anterior to the coronal suture. He was treated as an out-patient at another hospital, but ultimately applied at the Richmond, when he was admitted, several weeks having elapsed from the date of the injury. He soon presented brain symptoms, became convulsed and comatose, and it was determined to trephine. A

[1] The substance of this paper was embraced in a report to the Adjutant-General of the State of New York, with view to the formation of a hospital corps in the National Guard of that State.

An order for the detail and instruction of company bearers has already been promulgated, and it is hoped that ultimately a distinct hospital corps will be organized on lines herein indicated.

small fracture was found under the scar; the dura mater bulging into the wound, an exploring needle was introduced to the depth of an inch and a half, and pus was at last found. The dura mater was then incised, and one ounce and a half of pus was evacuated. The patient completely recovered, and is now attending to his ordinary work. The paper noted eleven other cases of abscess which had been operated upon by various surgeons, and discussed the questions involved. The third case was brought forward by Dr. C. B. Ball, of Sir Patrick Dun's Hospital, and the patient was also produced. The lad had been struck with a small knife over the squamous portion of the left temporal bone ten days before admission. The wound was healed, but he had some aphasia. Pain in the head and ear supervened, and the aphasia increased. It was determined to explore. He was trephined some weeks after the original injury. A wound was found in the dura mater corresponding to the puncture of the bone. A sinus forceps was passed in, the wound opened up, and some blood clot escaped. The patient was decidedly better, but next morning he was again aphasic. The wound was washed out, and more blood clot escaped. The aphasia almost disappeared, but two days later it returned, and the wound was again washed. After this the patient progressed favorably, and is now well. Dr. Ball pointed out the *rôle* of the brain lesion, as indicated by the various symptoms of aphasia. The group of cases was a very remarkable one, and the record of them cannot fail to influence the views of surgeons on the subject of brain surgery.—*British Medical Journal*, March 3, 1888.

The Treatment of Diphtheria by Creasote.—LEGROUX, in the *Archives de Laryngologie* of February 15, 1888, reports the following methods of treating diphtheria by creasote:

By atomization—

Creasote (1 to 100)	1 quart.
Alcohol	2½ drachms.

Pencilling the throat every four or five hours with

Glycerine	℥ 5.
Alcohol	℥ 2½.
Creasote	♏ 15.

Hypodermatically, in very severe cases—

Sterilized olive oil	parts 9.
Creasote	part 1.

From 1 to 3 minims of creasote may be injected into the hypochondrium.

Sixty-eight patients were treated, of whom thirty recovered; among those tracheotomized, one in three recovered.

The Medical Treatment of Typhlitis.—BOUCHARD advises morphia to quiet pain, with belladonna plaster locally, and large poultices over the painful part. Hot water enemata twice daily of a quart of water, to which are added sodii borat. grs. 75, and two or three teaspoonfuls of the following mixture: Tinct. benzoin, alcohol, camphorat. equal parts. Absolute rest must be enjoined. Purgatives should be used with great caution, magnesia is suggested.

For diet milk and lime water, in small quantities, to which is added a little yolk of egg—in short, food leaving little residue and not favoring fermentation. If the affection becomes chronic small blisters are beneficial—*Revue de Thérapeutique*, February 15, 1888.

Fatal Injury from Fall on the Feet; "Water-hammer" Shock.—BENJAMIN WARD RICHARDSON reports, in the *Medical Press* of February 22, 1888, the following interesting case: The first illustration of the kind to which my attention was specially directed occurred whilst I was one of the physicians to the old Blenheim Street Dispensary, an institution now long since of the past. A glazier who was repairing a first-floor window near the dispensary, slipped and fell; he came down upon the pavement straight upon his feet, "like a cat," as one of the witnesses said at the inquest, then he dropped to the earth and was taken up dead.

I was seeing the out-patients at the time of the accident, and was called to the unfortunate man. He was lifeless when I arrived, and although his fall had not been more than fourteen or fifteen feet, at the most, he was said to have died instantly, without the slightest trace of bruise or fracture of bone. He was considered a healthy and very steady man, and, except that he was of rather small stature and light build, he was well-shaped and strong. On the following day I made the post-mortem examination of his body. There was no external sign of injury, and every internal organ, including the brain, was quite natural except one. The pericardium was filled with coagulated bright red blood, which had escaped into it from a small rupture in, or rather through, the aorta immediately above the aortic semilunar valves. There was no evidence of structural disease in the coats of the vessel, and the rupture itself was nearly round, with smooth edges. It was about the size of a lace-hole in a shoe, and would have admitted a good-sized crow-quill; it was just above the centre of one of the segments of the aortic valve.

The cause of the fatal rupture in this case was due, I have no doubt, to a simple physical concussion, the like of which is sometimes met with in common machinery. When, suddenly, we turn the tap of a cistern of water, at a time when the water is running down the tube, we hear a noise—a smart rap—which working-men call "the water-hammer." Occasionally, at the moment when this noise is heard, the pipe bursts just above the stopcock, owing to the sudden arrest of the flow and the resultant pressure. It is precisely the same in the aorta under the circumstances detailed in the case of the glazier. The whole of the blood of the body in its course out of the left ventricle—with the exception of the little quantity which goes to feed the coronary circuit—has to ascend through the first part of the aorta, and when the semilunar valves close up below it the artery undergoes great dilatation. Ordinarily, the resiliency of the arterial tube is sufficient to meet the pressure, but if at the moment of strain there comes a percussion that will bring the volume of blood back upon the valves the water- or, in this example, the blood-hammer-stroke comes down with effective force, and either distends the segments of the valves driving them downward toward the ventricle with considerable tension and strain, or the arterial coat is torn. As a rule, nothing more happens than distention of the vessel; as an exception, the vessel gives way and the pericardium is filled, rapidly, with blood.

The Dangers of Simple Extraction of Cataract.—Derby, of Boston, in the *Boston Medical and Surgical Journal* of February 28, 1888, calls attention to the dangers of cataract operations, as follows:

The question as to what operation should be performed in an ordinary case of senile cataract is once more a prominent subject of discussion. At the late meeting at Heidelberg, as well as at the one held at New London, this matter engrossed much attention. More recently, Professor Schweigger, of Berlin, has published in Knapp's *Archives* an article on the return to the flap operation, in which the performance of iridectomy, the "needless maiming of the iris," as the author expresses it, is strongly denounced.[1]

The question at present under discussion is, therefore, the following: Do the modern discoveries of a reliable myotic, of an efficient local anæsthetic, and the adoption of antisepsis, justify a return to the principle of extracting senile cataract without the performance of iridectomy?

May not the operation, however, be restricted to certain cases, and are not certain special rules to govern the after-treatment? The writer has laid down the following principles for his own guidance:

1. He would reserve simple extraction for those cases in which the cataract is ripe, the nucleus large, the patient tranquil and amenable to discipline.

2. After the operation, the application of the bandage should be slightly delayed, the object being to ascertain whether the iris, once replaced, shows any tendency again to prolapse. If it does so, it is to be at once excised.

3. Eserine is to be applied directly to the eye immediately after the operation, and dropped in the inner corner of the eye, without separating the lids (as recommended by Schweigger) for the three following days.

4. Greater quiet on the part of the patient is to be insisted on than has been the case after the operation of Gräfe.

5. The eye needs to be inspected much sooner, certainly by the end of the third day.

And even if these or similar rules be followed, Derby cannot resist the belief that for the average surgeon, and in the present state of our knowledge, simple extraction at the best involves an element of danger that is wanting in the method of Gräfe. The successful extraction without iridectomy is uequestionably the more brilliant of the two methods, and the patient thus cured a more striking exemplification of surgical skill. A greater familiarity with the new operation may cause the risk to assume inconsiderable proportions. But some risk is likely always to remain. It is like the old question as to the relative advantages of ether and chloroform: the latter easier to transport, pleasanter to take, quicker in its effect, and occasionally alarming in its consequences.

The Treatment of Hydrophobia by Hyposulphites.—Newth describes his use of these remedies in septicæmia and kindred disorders as follows: I am in the habit of prescribing the hyposulphites in combination with bicarbonate of soda and sulphate of magnesia in peppermint-water. For children I simply give it with syrup and caraway-water. Though my experience is not sufficient to establish the value of this remedy decidedly, it is so far satisfactory that I unhesitatingly prescribe it in any cases where there seem to be symptoms of blood-poisoning. In aphthæ, for instance, it seems to work like a charm, and in boils, scrofulous abscesses, etc., it really appears to do great good. I have also prescribed it with success in diphtheria and puerperal fever. It seems to me that, as hydrophobia is without doubt a form of septicæmia, the hyposulphites might do good in this terrible disease. They certainly could do no harm, and, therefore, I would suggest a fair trial of this remedy, not only when the disease has developed itself, but as a prophylactic. After a bite by a mad dog I would give five or ten grains of the hyposulphite of sodium or magnesium (the latter is richer in sulphurous acid) for the first three or four days every four hours; then three times a day for a week; then twice a day for another week; then every morning early for one month; recommending a Turkish bath twice a week. When the disease has developed I would prescribe the hyposulphite every hour or every two hours, with vapor or dry hot-air baths, or prolonged warm-water baths containing some hyposulphite in solution. The hypodermatic injection might also be tried, especially if the patient is unable to swallow. In other cases the sulphurous gas might be given per rectum. By such means as these I firmly believe hydrophobia may be cured, and trust that those who have the opportunity to do so will try them.—*Lancet*, Feb. 18, 1888.

Convenient Combinations for Administering Hydrochloric Acid in Dyspepsia.—The *Revue Générale de Clinique et de Thérapeutique* of February 9, 1888, contains a number of formulæ for the administration of hydrochloric acid, from which we take the following:

Hydrochloric acid lemonade:

Aquæ	O1¾.
Syrup. simpl.	℥ 25.
Acid. hydrochlor.	♏30 to 60.
Spirit. limonis	♏ 15.

A half glass or glass after meals.

A digestive and laxative potion may be ordered as follows:

Acid. hydrochloric. . . .	♏ 15.
Syrup. simpl.	℥ 7½.
Vini rhei	℥ 25.

Of which the dose may be varied as indications demand.

Hydrochloric acid and cocaine may be given as follows:

Syrup. menth. piper. . . .	℥ 7¾.
Acid. hydrochloric. . . .	♏ 15.
Cocain. hydrochlorat. . . .	gr. 1½.

Which is prescribed by Huchard in varying doses for gastric pain in eating.

West prescribed for children the following mixture, in doses of one to two small teaspoonfuls:

Acid. hydrochloric. dil. . .	♏ 15.
Syrup. aurant. cortic. . . .	♏ 75.
Tinct. aurant. amari . . .	♏ 45.
Infusion. cascarillæ . . .	℥ 10.

Hydrochloric acid is given to increase the acidity of the gastric juice; to dissolve phosphates and alkalies; to contribute to the formation of chloride of sodium in the

[1] Archives of Ophthalmology, vol. xvi. p. 455.

organism. In general terms, it is given before meals to assist in overcoming gastric atony; after meals to remedy hyper-alkalescence.

The Influence of Various Foods on Respiratory Activity.—Richer and Hanriot conclude from their experiments that the taking of food, especially the hydro-carbons, greatly increases the gaseous interchanges of respiration. Nitrogenous and fatty foods affect respiratory changes very little. Food rich in substances forming gases absorb oxygen freely and produce carbon dioxide abundantly. Muscular activity or repose affects gaseous interchanges in no great degree.—*L'Union Médicale*, February 18, 1888.

Suicide with a Pin.—Thomson reports in the *Medical Press* of February 22, 1888, the following extraordinary case:

The deceased was admitted to the Richmond Hospital, but was found to be dead. He had been arrested as a lunatic running about the street in his shirt. On examination of the body, the head of pin was discovered in the fifth intercostal space, two and a half inches from the nipple—downward and inward. The pin had traversed the pericardium, and wounded the anterior wall of the left ventricle. The pericardium contained seventeen and a half ounces of blood fluid, and there was a small rent in the wall a quarter of an inch in diameter, which was filled by blood clot. The surface of the ventricle in contact with the pin was torn to the extent of nearly an inch; a small vein was also wounded; all the internal organs were congested; the urine was albuminous.

Death from Sepsis after Perineorrhaphy by Tait's Method.—Mundé, of New York, in commending Tait's operation and describing successful cases, reports a case of septicæmia, which occurred as follows:

Last December a patient presented herself at my office with a large complete laceration of the perineum. I admitted her into the Mount Sinai Hospital, and on December 28th did Tait's operation, under the most careful antiseptic precautions, irrigating the wound frequently with a 1 to 10,000 sublimate solution. Deep silkworm gut and superficial catgut sutures were used. The patient had a slight rise of temperature, and complained of much pain on the next day, but as there were no local evidences of inflammation I attributed the symptoms to nervousness (she was very hysterical) and reaction from the operation. I was then suddenly taken ill and confined to the house for three days. A messenger sent to the hospital brought me the news that the patient had a slight rise of temperature, but did not seem very ill. But as soon as I saw her, when able to go out, on the fifth day after the operation, I recognized septic infection, and at once removed the stitches. A large yawning, sloughing cavity presented itself, which was diligently and frequently irrigated, and the patient stimulated by all possible means; but she died of a low form of septic poisoning on the tenth day after the operation. Out of several hundred perineorrhaphies performed after the old method no such accident, indeed no febrile reaction had occurred to me. I do not see how I could have operated more aseptically; it is true, the stiches should have been removed sooner, and would have been had I been able to see the patient. But septic infection ought not to have occurred at all. I have heard of its taking place in the practice of other operators, but I had so far escaped, and I did not wish to destroy the success of the operation when septic infection was yet doubtful. Still, the fact remains that so deep a wound into so highly absorbent tissues may be more liable to septic influences than the more superficial wound of the old operations.

My confidence in Tait's method is, however, so strong that I propose to perform the operation next week; but I shall most carefully watch for a rise of temperature, and rather remove the sutures early than risk the life of my patient from septicæmia. I would add one caution, and that is, not to divide the recto-vaginal septum to a greater depth than half an inch, which gives a large enough surface for union.

Antiseptics for Use upon the Skin.—The *Revue Générale de Clinique et de Thérapeutique* of February 23, 1888, gives the following formulæ for antiseptics appropriate for use upon the integument:

A lotion—

Acid. thymic.	1 part.
Alcohol.	4 parts.
Aquæ destill.	ad. 1000 parts.

Glycerole of boric acid—

Glycerole of starch	10 parts.
Boric acid	1 part.

For chafing and perspiring feet:

Acid. salicyl.	3 parts.
Starch	20 parts.
Powdered chalk	87 parts.

may be employed.

Cocaine in Urethral Operations.—Dr. Alexandro Settier gives in a Spanish medical journal his experience of the employment of cocaine as a local anæsthetic in operations of various kinds on the urinary organs. He has used it in nine cases of internal urethrotomy, one divulsion (forcible dilatation), two urethro-perineal fistulæ operations, one rapid lithotrity, three circumcisions for complete phimosis, and two extirpations of vegetations. In none of these eighteen cases has he observed any serious toxic symptoms such as have been described by Peck, Reich, Bellyarminoff, and Keyser. In three cases, however, the patients complained of severe headache and great dryness of the mouth. The solutions used were generally of the strength of 5 or 6 per cent. For internal urethrotomy a variable quantity (in one case as much as five drachms) of the solution was introduced into the urethra, as near as possible to the seat of the stricture, by means of a catheter in the form of a simple tube open at both ends. This solution was allowed to remain in contact with the tissues for twenty-five minutes before the operation was commenced. In all cases of this description the cocaine succeeded admirably, the patient feeling no pain at all except at the moment when the stricture was divided, and then only in a very slight degree. The action of the drug was much less satisfactory in the single case of forcible dilatation, but the pain lasted a much shorter time than it does in similar cases where no anæsthetic is employed. No effect was produced in the cases of urethro-perineal fistulæ. In the lithotrities, circumcisions, and the opera-

tions on preputial vegetations very good results were obtained. In the two latter classes of cases the cocaine was combined with glycerine or vaseline in the proportion of 1 to 15; this was applied over the surface of the prepuce. In one of the phimosis cases an 8 per cent. solution was likewise injected under the prepuce. This, however, caused a good deal of headache. Dr. Settier remarks on the importance of keeping the solution a long time in contact with the mucous membrane of the bladder in cases of lithotrity, in order to prevent contractions of the organ taking place during the process of aspiration.—*Lancet*, February 25, 1888.

Punctiform Parenchymatous Hemorrhage in Railway Injuries.—Vibert, in a recent medico-legal study of railway injuries, reports an interesting observation in an accident on a French railway. Among eighteen persons killed were five whose bodies presented no fracture, wounds, dislocations or external lesions. Post-mortem examination revealed appearances in the tissues resembling the phenomena of asphyxia, and in particular very numerous punctiform hemorrhages in the viscera and tissues of a portion or the whole of a segment of the body. This phenomenon was also present in cranial fractures. Vibert considers it due to lesions of the nervous centres, probably the medulla.—*Gazette Médicale de Paris*, February 18, 1888.

The Mode of Action of Corrosive Sublimate in Poisoning.—In exhibiting before the Berlin Medical Society specimens from cases of poisoning by corrosive sublimate, Virchow explained its effects as follows: He had raised the question, How it happens that in one case of sublimate poisoning deposition of lime takes place in the kidneys, and in another not? This depends on the mode of poisoning. When an animal is poisoned with sublimate, a distinction may be drawn between two factors: 1. The animal receives an injury from the sublimate as such, which may be compared with any other metal, such as gold, iron, etc.; and, 2, by the sublimate the tissue change is altered, the quality of the blood undergoes a change, its alkalescence is diminished by lactic acid, which at once appears in it. Lactic acid is a great enemy of the bones, prevents their formation and dissolves them. Sublimate forms lactate of lime, and this is excreted through the kidneys. This excretion takes place through sound kidneys; by the introduction of the poison, however, they become diseased, and as the excretion cannot be effected under these circumstances, the lime salts remain (retained in the kidneys), and the patients die, not because they have lime in the kidneys, but they have died, and had lime in the kidneys. In these cases the question is one of the amount of lactic acid, and the condition of the kidneys.—*Medical Press*, February 22, 1888.

Antipyrin and Cocaine, for Dental Anæsthesia.—Martin has obtained good results by injecting this solution into the gum about a painful tooth:

Cocaine hydrochlorat.	$\frac{3}{5}$ gr.
Antipyrin.	6 grs.
Aquæ destill.	30 ♏.

The effect is obtained more slowly than when cocaine is used alone, but continues longer, and the risks of cocaine are avoided.—*Revue Gén. de Clin. et de Thér.*, February 23, 1888.

Forced Respiration in Profound Narcosis.—Fell, of Buffalo, reports a case of profound narcosis from which the patient was rescued after thirty hours of constant labor. Artificial respiration failing, tracheotomy was performed, and forced respiration by a bellows-apparatus devised by Dr. Fell was performed. Life was saved, in the opinion of the reporter, by this means. This is the third case so treated by Dr. Fell, with successful results. —*Buffalo Medical and Surgical Journal*, March, 1888.

The Use of Mercury in the Early Stages of Syphilis.—Jonathan Hutchinson writes as follows in a paper on this subject in the *British Medical Journal* of February 25, 1888: My wish has been to draw attention to a clinical fact which, although hitherto much ignored, or even denied, must have been for a long time more or less under the cognizance of all engaged in the treatment of syphilis according to modern rules. The fact to which I refer is that the early use of mercury does not only greatly shorten the duration of the primary phenomena, but that it also much modifies, and in many instances entirely prevents, those of the secondary one. I have, indeed, ventured to assert that, when circumstances favor the febrile stage of the exanthem, syphilis may be rendered wholly abortive. If we can accept this proposition, I feel sure that we shall have gained a step in the orderliness of our future work.

Ergot of Oats.—Bousquet has observed, in the province of Oran, the effects of this substance as used by the Arabs. It is commonly employed by native accoucheurs and Arab women for the purposes for which we employ ergot of corn or rye.

Bousquet employed it in nine cases, in the form of powder, for uterine atony and hemorrhage. Its specific effects were as pronounced as those of corn ergot, and in addition it exerted a general tonic effect which was most salutary.—*L'Union Médicale*, February 19, 1888.

Poisoning by Antipyrin.—Jennings reports, in the *Lancet* of February 25, 1888, the following instructive case:

Miss X., sixty-seven years of age, consulted me for rheumatoid arthritis, affecting chiefly the hands. Her maternal grandfather was gouty, and she has always suffered more or less from arthritic symptoms in the knee-joints. The heart is peculiar in that it normally beats only about thirty-five pulsations to the minute. This lady has recently complained of swelling of the hands, without positive pain, but with sensations of pricking, which interfered with her usual occupation, that of preparing and classifying specimens relating to natural history. (It may be mentioned that she is a distinguished conchologist, well known in scientific circles.) I recommended her to take antipyrin, which seemed to be the more indicated as she had already been relieved on a former occasion of rheumatic troubles by salicylate of soda, which had, however, left her greatly weakened. The treatment was commenced on January 23d, and for eight days she took thirty-seven and a half grains of antipyrin daily, when on the 31st she was surprised to see that she was covered with erythematous patches on the arms, and at the same time felt that her eyes were uncomfortable.

The following night she scarcely slept at all; the feet were icy cold; no nausea; no giddiness. The next morning she discovered that her face was red and extraordinarily swollen. The eyelids were almost closed by the swelling, and left only a narrow slit for vision. Pushing her investigations further, she saw that the rash was general and of the color of pomegranate, arranged in patches the size of a threepenny piece, separated one from another by intervals scarcely noticeable at first sight, but distinctly recognizable upon closer examination, and about a millimetre in diameter. The patient had no appetite, and did not attempt to eat; she only took a small quantity of tea during the day, which she passed sitting by the fire. Curiously enough, this condition gave rise to no suffering; all that was felt was a strange sensation "as if the inside of the body was filled with ice." There was but little itching. The following day the condition was as follows: The eyes, which first attracted my attention, were the seat of slight catarrhal conjunctivitis—already, however, on the decline. There was irritation of the nasal fossæ, and hoarseness of the voice. Indeed, one might have thought of intoxication by iodide. The puffiness and swelling of the face had partly subsided, but the rash remained on the trunk and extremities. The pulse was twice as fast as usual, 76 to the minute; but notwithstanding this, for the patient, almost febrile acceleration, the temperature was lowered, the surface remaining cold. Beyond a slight buzzing in the ears, there was no other sensorial disturbance. As treatment, I merely prescribed small doses of tincture of belladonna. Next day the pulse was 56. The catarrhal condition of the oculo-nasal membrane was decreasing. Since then it has disappeared, and the eruption is gradually passing away. But the patient still suffers from considerable prostration and intermittent sensations of cold.

The Treatment of Whooping-cough.—SIMPSON found the following prescription most successful in treating 240 cases of whooping-cough among coolie children; mortality from the disease, nil:

R.—Acid. carbolic.	. . .	♏j to ij.
Vin. ipecac.	. . .	♏iij to v.
Acaciæ gumm.	. . .	grs. v to x.
Syr. simplicis	. . .	ʒss to ʒj.
Aq. camph.	. . .	ad. ʒj to ʒij.

Every three hours.

—*Provincial Medical Journal*, March 1, 1888.

Cocaine Poisoning.—DÉJERINE is quoted by the *London Recorder* of February 20, 1888, in his description of the following interesting case: The patient was a dentist, twenty-six years of age. M. Déjerine found him in a semi-comatose state, with generalized muscular contraction of the arms and legs. The arms were slightly bent, the legs were stretched out. Patellar reflex action was not discernible, owing to contraction. The pulse was quick, but regular (120); the breathing hurried. The eyes were closed, the pupils dilated and insensible to light. There was complete unconsciousness. The following lesions were detected on the skin: There was a pustular crusty eruption, consisting of pustules the size of a pea, covered with a blackish-gray, dry scab on the anterior external surface of the two arms, and on the anterior part of the legs and thighs. This eruption resembled the scabs of syphilitic rupia. The patient had suffered from blennorrhagia. On returning to consciousness the patient walked about with closed eyes, on account of the painful sensation caused by light on the eyeballs. He gave the following particulars concerning the cause of the attack: Six weeks previously he began to administer subcutaneous injections of cocaine to himself. He began with doses of one-sixth of a grain. He increased the quantity gradually until he employed seven and a half grains. The injection produced agreeable sensations and sexual desires, followed by ejaculation. The evening on which the attack above described took place he had injected fifteen grains of cocaine at ten o'clock. He employed three syringes and a warm solution. At the third injection he fell down in an unconscious condition. On the following day Dr. Déjerine again examined the eruption, which consisted of limited gangrenous areas of the epidermis, resulting from the injections with cocaine, which the patient had introduced into and not under the skin. At the spot where the injections were made white cadaverous spots were apparent; these were insensible to the touch. The patient stated that when M. Déjerine pinched him in different places during the state of coma he was aware of the fact, but that he felt no pain whatever. He was, therefore, sensible to the contact of an external object, but insensible to pain. The patient recovered. He has ceased to employ cocaine. M. Déjerine considers that if the patient had not gradually accustomed himself to progressive doses of cocaine, the dose of fifteen grains would have proved fatal.

Injection of Ergotin into the Tissues of the Cervix Uteri.—SCHUCKING reports, in the *Centralblatt für Gynäkologie*, No. 8, 1888, his method of injecting ergotin into the cervix as follows:

He uses a carefully disinfected needle; the solution of ergotin is freshly made and undiluted, and the quantity is one-fourth to one-third the contents of an ordinary hypodermatic syringe. The needle should not be inserted deeper than a fifth or a fourth of an inch into the anterior or posterior lip of the cervix. He has never seen ill effects, in pain or any injury, follow. He does not favor injections made into the body of the uterus, or into a tumor of the uterus; ill effects reported from such injections he considers due to failure to disinfect properly the needle used.

The Anti-tubercular Action of Iodoform. — ANDRASSY, BRUNS, and NAUWERK are quoted by the *Centralblatt für die med. Wissenschaften*, No. 8, 1888, in reporting their results with the use of iodoform in tuberculous disease, generally in tuberculous abscesses, by drainage and injection of iodoform in emulsions with glycerine. Andrassy treated twenty-two abscesses with ten per cent. iodoform emulsion of equal parts glycerine and water. The injections averaged two or three for each case, repeated in about two weeks, two and a half drachms of iodoform being used at each injection. Twenty of the abscesses treated were permanently cured.

Bruns and Nauwerk cured forty tuberculous abscesses out of fifty-four which were treated. In eight cases portions of the pyogenic membrane were excised and examined for bacilli; these examinations showed a non-irritant, but anti-tuberculous action of the iodoform.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

EXSECTION OF EXTRAUTERINE PREGNANT CYSTS.

ALTHOUGH there are forms of extrauterine pregnancy in which the Fallopian tube is not a factor, as is clearly demonstrated by the remote location and attachment of the placenta in well-authenticated cases, the great majority of ectopic cysts will be found to be, or to have originally been, tubal. There is nothing in the inherent vital power of a human ovum, to make an original abdominal development of it impossible; the only thing strange about it is, that this so rarely happens.

An ovum has, prior to its attachment to some vascular base, an independent life, like that which exists in a seed, a bud, and a bird's egg. This life continues long enough for the ovum to travel from the ovary into the uterine cavity, and there form an attachment, by which its independent power of living is no longer required, and it consequently ceases. Is there any reason why this independent living and moving body cannot do in the abdominal cavity what it does in the uterus and Fallopian tube? Heat starts the process of incubation in a bird's egg; take away this stimulus long enough, and its reapplication only produces decomposition; the inherent life is destroyed by the interruption in the development of the bird. Reasoning analogically, a human ovum once attached to the lining of the Fallopian tube, has lost its independent life, and can no longer live, if *entirely* separated and cast out, by the bursting of the said tube; to continue its development below the tube, or within the abdominal cavity, its vascular dependence must not be interrupted; its blood supply is now essential to life. If, then, we find a placenta attached to the abdominal wall on a level with the umbilicus, as in the celebrated Weist operation, of Richmond, Indiana, 1884, we have a right to infer that this placenta did not commence to develop in the Fallopian tube, and was thence transferred to the abdominal wall. The same may be said of other cases that are historical, where the placenta was found at still more remote and singular locations, high up in the abdominal cavity. There are those who would have us believe that all abdominal pregnancies were originally tubal; but this is much more difficult to credit than that some are *ovarian* and others truly *abdominal*, as the great majority believe.

The large majority of cases being Fallopian, and in their early stage of growth capable of exsection without very great difficulty or danger, it becomes a question whether this should not be done to secure the woman against the risk of death from the laceration of the cyst and resulting hemorrhage, an accident which is most common, according to Parry, from six weeks to three months after conception, the height of danger being at eight weeks. More recent observers place this point at ten weeks. In considering this question of the propriety of exsection, as advocated by Martin, of Berlin, and others, we must carefully take up two points of vital moment, viz.: 1. Can the presence of an ectopic fœtal cyst be detected prior to laceration? 2. Shall fœticidal measures be adopted; or the operation of exsection in preference?

We must admit that a differential diagnosis is not absolutely positive; but there have been such diagnoses made, and exsections performed successfully, as we can bear witness to. Mr. Tait denies that a diagnosis can be made prior to rupture, which may be correct so far as his personal observation has extended; but American gynecologists, who have taken time to examine cases historically, as well as by touch, make much more positive claims. A thin hand with long fingers and a delicate tactile sense, are essentials to perfection in examining the pelvic organs. There is certainly a great difference in operators as to their delicacy of touch with a probe, sound, or the finger, and what may be quite possible with one, is impossible with another. Quite recently we heard a surgeon charged with untruthfulness, because he claimed a power in differential

diagnosis by the touch, which he honestly believes, from repeated tests.

Granted that the diagnosis is correct, should the life of the fœtus be destroyed by galvanism, and it be possibly a cause for future trouble, as has several times happened; or should the cyst and its contents be exsected, so that there shall be no foreign body left, as a centre of inflammatory mischief? Recent discussions by leading gynecologists, show that there is a decided opinion held by many, that exsection is to be preferred, in many cases, and particularly where the fœtus is of a size to give trouble. Martin advocates this operation at all ages of the fœtus, and has removed with success to the mother, a moribund child, with much of the cyst and placenta, at seven months.

It should be remembered that it is only in exceptional cases of advanced ectopic pregnancy that *entire* exsection of the sac and contents can be accomplished. This was done in October last, by Breisky, of Vienna, in a case of intra-ligamentous gestation at full period, and both mother and child lived. But in thirty cases of primary laparotomy, for the saving of child and mother, the placenta was cut into in the line of abdominal incision five times. In such subjects the placenta cannot be removed, unless, as in the Breisky case, where it had no attachment to the abdominal wall. In a few instances the sac has been exsected after fœtal death in the latter months of gestation; but here, again, the location of the placenta among the intestines and elsewhere, has rendered its removal impossible, in the great majority of cases. The Martin method will have to be confined almost exclusively to tubal cases, and to these chiefly, in the early months, where its application may become one of much value. Martin is said to have operated upon twenty cases, with excellent result.

SEWAGE IN WATER-SUPPLIES.

One of the most notable papers read at the Sanitary Convention held in Philadelphia, in May, 1886, under the auspices of the State Board of Health, gave a clear exposition of the specific dangers to the public health attending the use of unwholesome water-supplies. The point of greatest interest brought up for discussion was the connection between sewage in water-supplies and the prevalence of typhoid fever.

The influence of a sewage infected with the typhoid cause is, of course, well demonstrated by many and constantly recurring investigations into the origin of local epidemics; but in the paper in question the position was taken, by its author, Dr. Smart, of the Army, that on account of the prevalence of typhoid fever in our rural, as well as urban districts, all sewage entering a river or lake must be regarded as an infected sewage and capable at some time, if not at all times, of spreading the disease by the use of the water from these infected sources. The continued prevalence of typhoid fever in our communities was referred, among other causes, to the use of water which contained sewage; and the medical history of several cities, as Philadelphia, New York, Brooklyn, Boston, Baltimore, and New Orleans, was brought forward to show that the typhoid death-rate is proportioned to the carelessness of a community in regard to its water-supply. It was demonstrated that as surely as a water free from sewage is introduced into a city, in place of that from foul streams or wells in contaminated soils, so surely does the typhoid-rate fall in a manner which leaves but one interpretation, for lest this fall should be attributed to the sewerage system which usually follows the systematic distribution of water, the history of Baltimore, which built no sewers, shows no exception to the general rule. The only way to reduce the typhoid-rate, from 30, 40, 50, or 100, annually per 10,000 living, to the small figure which would represent the action of other and as yet unsettled causes, was held to be by obtaining a water-source untainted by sewage and carefully preserving it from subsequent pollution. As this conclusion ran counter to the interests of the capital already invested by many municipalities in perfecting their water-supplies, the points of the argument supporting it were not utilized in a sanitary campaign against sewage. Indeed, health-officers were afraid to open up the question of sewage-inflow into their streams lest their necessary antagonism to this invested capital should react to the detriment of other suggested sanitary improvements which required assistance for their accomplishment.

And now there comes from the other side of the Atlantic the testimony of Vienna in support of that given by our American experience. The *Revue d'Hygiène* of January 20, 1888, in a paper by M. Mosny, brings up the water-supply of that city for comparison with the ravages of typhoid fever. From 1851 to 1874, while well-water of an impure character and river-water from the Danube were used, the deaths from typhoid fever ranged from about

100 to 340 annually out of every 10,000 living; but the introduction of a spring-water supply in 1874 was immediately followed by a fall in the rates to 50; and the gradual disuse of the former sources has brought the rate for the past three years down to about 11. As the sewerage system was in existence during the period of high rates, the fall since 1874 is necessarily referred to the use of a water which is free from sewage; and this view is strengthened by the occurrence of an epidemic in 1877, which, it is claimed, was caused by a return to the water of the Danube on account of the spring supply failing by the freezing of certain of its sources. The sections of the city affected by the epidemic were those in which the river-water had to be largely used. These facts so impress M. Monsy that he announces water to be the principal agent in the transmission of typhoid fever, and claims that the only thing needful to uproot the disease from a city in which it is endemic, is to distribute a pure water to its inhabitants.

The city that has effected this desirable change comes forward with its experience; but it is too much to expect that others will profit by it so long as the expenditures involved in such a change are not called for by a death-rate beyond that which, preventible though it be, we bear by habit without complaint.

The malady to which the late Emperor of Germany succumbed, according to the *British Medical Journal*, was renal colic, to which he had been subject for several years past.

Bellevue Hospital Medical College, at its annual commencement last week, conferred the degree of M.D. on 144 graduates; the Woman's Hospital Medical College, of Philadelphia, on 27; the University of Buffalo on 44; the University of Nashville on 82; Memphis Hospital Medical College on 54; Miami Medical College of Cincinnati on 21; Southern Medical College of Atlanta, Ga., on 32.

At the annual meeting of the Medical Society of London, held March 3d, it was announced that the Fothergillian prize of a gold medal of the value of twenty guineas, had been awarded to Dr. Hobart A. Hare, of Philadelphia, for his essay on "The Pathology, Clinical History, and Diagnosis of Affections of the Mediastinum other than those of the Heart and Aorta."

We learn, with great regret, that Sir Henry Acland has recently undergone the operation of removal of the left eyeball on account of hemorrhagic glaucoma. We trust that this will not preclude his visit to this country this summer, which, we are informed, he had in contemplation.

In our "News Items," last week, we quoted from the *Lancet* the statement that representatives of M. Pasteur had sailed for New South Wales to enter into competition for the prize of £25,000 offered for the depletion of the plethora of rabbits in that country. Almost simultaneously there comes from the antipodes the announcement that the adoption of M. Pasteur's remedy will be resolutely opposed in some parts of the colony. A government official, by the name of Abigail, has declared his antagonism to the introduction of the chicken-cholera microbe, as being more fraught with danger than the pest of the rabbits. It is possible that the French envoys may have taken their long voyage in vain.

Science has addressed inquiries to twenty-eight medical schools in the United States, asking their attitude regarding the germ theory of disease, and what, if any, facilities for teaching bacteriology each affords. The replies indicate that in but one instance was a positive denial avowed. All teach the germ theory, and demonstrate bacteria to a greater or less extent.

Senger reported at a recent meeting of the Berlin Medical Society that he had examined ten carcinomata by bacteriological methods, without finding a bacillus which he considered in any way a cause of the carcinoma. It is stated that Koch agrees with him in considering Scheurlen's cancer bacillus as a harmless bacillus, growing in the potato-culture material.

Dr. E. H. Bartley, formerly chief chemist to the Brooklyn Board of Health, has reported to the Secretary of the State Board upon the adulterations of spices practised in the spice mills of that city. Among the articles used to mix with pepper, mustard, and ginger, he found burnt nut-shells, charcoal, corn meal, and wheat middlings. This report has proved to be of the nature of a bomb-shell in the camp, as almost nothing is being done in New York State for the sanitation of the food supply.

The Canada Health Journal has become *The Prophylactic*, and has moved its office of publication

from Toronto to New York City. This journal is ably edited and wears the aspect of growing prosperity.

Medical Science, a recently established medical journal published in Toronto, has been received. It will appear monthly; its first number contains several articles by well-known Canadian physicians, and an address by Prof. Vaughan, of the Michigan University.

DR. EDWIN N. CHAPMAN died in Brooklyn, N. Y., March 2d, in his seventieth year. He was born at Ridgefield, Conn., in 1819. He was graduated from Yale in 1842 and from Jefferson Medical College in 1845. He was formerly the Professor of Materia Medica in the Long Island College Hospital, and the author of many pamphlets, and one book, a treatise on "Hysterology" (1872). He was a frequent contributor to the medical journals and to the proceedings of societies. One of his papers, in 1863, on the almost specific power of alcohol over diphtheria, attracted wide attention and a considerable following. His views were reiterated in 1877, when he claimed to have treated eighty-five successive cases of that disease, by alcohol with quinine, with not a death. He was a character of great originality, geniality, and enthusiasm; his quaint sayings were the current coin of the local profession about a generation ago. His death was by paralysis, following an apoplexy that disabled him about two years ago.

REVIEWS.

A MANUAL OF PHYSIOLOGY FOR STUDENTS OF MEDICINE. By GERALD F. YEO, M.D., F.R.C.S. Third American from the Second English Edition. Philadelphia: P. Blakiston, Son & Co., 1888.

THE appearance of another American edition of this well known and useful book is an evidence that it is one of those books which not only receive popular favor by reason of the first impression they produce, but also possess that which many works of its class lack, namely, a clear manner of making a statement and at the same time the advantage of doing this in a concise form. While, owing to its size, general discussions are of necessity left out, the author favors those views most commonly accepted so pointedly, that the student does not find himself at the end of a chapter with a confused jumble of theories, but one dominant idea to which he can cling with some feeling of security. Those of our readers who have used Yeo's book know of its value so well that anything we may say is unnecessary, and we think to the busy practitioner, who wishes to refer to a doubtful point, or to the student who wishes but one fairly positive statement of a fact this manual will prove well worth its cost.

SOCIETY PROCEEDINGS.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

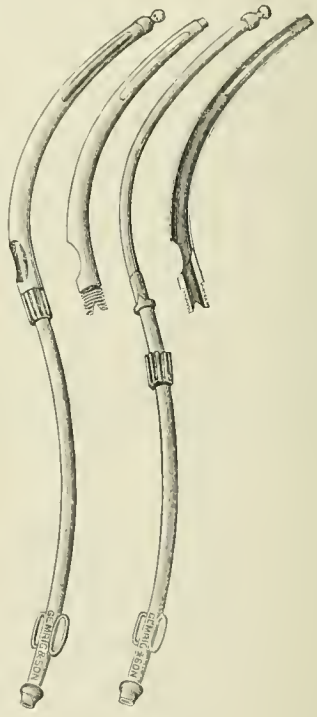
Stated Meeting, March 1, 1888.

THE PRESIDENT, THOMAS M. DRYSDALE, M.D., IN THE CHAIR.

DR. H. A. KELLY exhibited

AN ASEPTIC TWO-WAY CATHETER.

A two-way catheter, which will conduct and discharge water and solutions with the utmost freedom, and at the same time allow of perfect and ready cleansing after use, is a great desideratum. In the light of the antiseptic surgery of to-day, the use of such two-way catheters, as were commonly found in the surgeon's bag a few years ago, is in the highest degree dangerous, owing to the necessarily painfully tedious process of cleansing, and the impossibility of ever being able to assure ourselves that they are clean.



The catheter, as constructed by Dr. Kelly, consists of three parts. First the delivery tube, which conducts the stream from the hose connected with the reservoir into the uterus. This tube is well curved, and at its entrance is furnished with a knob to hold the hose better. Its extremity ends in a button, with a series of holes around and a little below the outer margin in the form of a rose, so placed that the stream is thrown out on all sides, and directed a little backward. The remaining two pieces are the two lateral halves of the *exit* pipe, which are attached very simply by entering at each end in the shallow collar under this *rose*, bringing them together around the inlet pipe and screwing the nut down on the thread on their upper end.

Each side has a fenestra in it, near the point, and is scooped out near its upper end, so that when the two are fitted together, there is a good-sized hole there.

When in use water flies with force from the holes at the end, washes with it débris and fluids, which enter at once the large fenestra on the sides, are washed down and out of this large hole into the receptacle. When out of use the cap is unscrewed, the halves fall apart, and every part which has come in contact with infection is at once exposed and readily cleaned.

The interior ought to be as highly polished as the exterior. Mr. Gemrig, of this city, has made these instruments for Dr. Kelly in a very satisfactory manner.

Dr. Kelly also exhibited a

COTTON PACKER.

Dr. B. C. Hirst showed

A PARIETAL BONE PRESENTING A SPOON-SHAPED DEPRESSION,

taken from an infant that died about two days after birth. The labor had been a difficult one, terminated by the forceps; the child had presented by the vertex in R. O. P. position; the pelvis was slightly flattened; head large, O. F. circumference 36½ centimetres. At the corresponding point internally there was a deep broad depression of the brain substance. The child apparently died from congestion of, and serous effusion into, the brain.

Dr. William Goodell remarked that Ambroise Paré had compared these depressions to the indentations on kettle-drums. The indentation in this case was very typical. After turning in the flat and narrow pelvis, these indentations were very marked. They occupied then the temporal region and not the parietal; the shorter bitemporal diameter being the one implicated. Hence, in turning, two mechanical advantages result, the small end of the cephalic wedge offers at the conjugate and also a cephalic diameter shorter than the biparietal.

Dr. John C. DaCosta wished to know if Dr. Goodell thought turning could always be done in these cases. He spoke of a case which had occurred in his practice where the bone was much more depressed than in the specimen shown. The whole left side of the head was bulged in by a large fibroid of the uterus which fitted into the depression like a mortise and tenon joint. The pelvis was of good shape and roomy, os uteri wide open and soft, and yet the head, which was at or above the superior strait, in L. O. A. position, would not descend on account of the tumor. As the woman was in good condition, and nothing seemed to be going wrong, he let her alone for a time. After a little while, by the aid of some manipulation, the head began to unlock from the tumor, and rotated from O. A. to O. P. position, and the child was delivered alive. This case could not have been turned, as the membranes had ruptured and the uterus gripped the child's body itself, and even if it could have been, there would probably have been a dead baby from pressure on the cord during the long delay that would ensue in delivering the head, as the tumor would most likely have locked under the baby's chin. The forceps could not be put on, on account of obstruction to the left side by the tumor.

Dr. Goodell thought that Dr. DaCosta would have had less trouble if he could have turned the child. He did not think the neck would have been caught. He had been speaking before of the mechanical advantages only, and not of the difficulties in the performance of version.

Dr. Goodell presented

A SPECIMEN OF HYDRO-SALPINX.

It was the largest specimen he had ever seen; although he had met with much larger specimens of pyo-salpinx. The case had been treated by many gynecologists, and the true condition had not been recognized. There had followed the operation a complete relief from pelvic pains, but menstruation had continued up to the present time. The periods were, however, becoming less frequent. Since it is contended by some eminent surgeons, that when menstruation continues after the removal of the uterine appendages, some of the ovarian stroma must have been left behind, he wished to call the attention of the Society to the complete extirpation in this case of both ovaries and tubes. Although the former were more or less adherent, it was evident from the specimen that not a particle of ovarian stroma was left behind.

Dr. M. Price said he had seen two cases in his practice where the menstrual discharge did not cease after the removal of the appendages. In one case it lasted for a year and a half, in the other six months. He had no doubt that Dr. Goodell's case would show the same result. There was but little doubt in the mind of most operators that the removal had not been complete.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 15, 1888.

The President, A. Jacobi, M.D., in the Chair.

Dr. Frederick R. Sturgis read a paper on

SOME QUESTIONS IN CONNECTION WITH SYPHILIS HEREDITARIA TARDA.

He remarked that the subject is one of much interest, not only to the syphilographer, but also to the general practitioner, especially on account of its relations to the etiology of many cases met with. In certain instances the agency of syphilis is suspected, without the physician's being able to prove the actual presence of this disease. It is only very recently that the phenomena of late hereditary syphilis have been at all appreciated by the profession. During the last twenty years much has been accomplished in clearing up the matter, but notwithstanding all the advances that have been made in this direction, many points still remain unelucidated. The question is still asked, Can hereditary syphilis remain latent for years? Until recently this was supposed to be a fact in certain exceptional cases of acquired syphilis; but the weight of evidence now shows beyond question that such a thing never occurs. Vidocq was the first to point out this mistake, and it is the generally accepted opinion at the present day in cases apparently of this kind that other and minor manifestations of syphilis always precede the so-called tertiary symptoms. There is always an initial lesion, although no trace of it may afterward be found.

It was at one time supposed that in all cases of hereditary syphilis the disease shows itself at birth, but the fact is now recognized that many cases occur in which

the children are apparently perfectly healthy when born. Statistics show, however, that in a large proportion of cases syphilitic lesions make their appearance before the end of the third month. Of 249 cases collected by Diday and other authorities, the disease showed itself in 118 by the end of the first month, in 117 between this time and the end of the third month, and in 14 later than the third month. Of Diday's own cases, in two the lesions did not appear until after the first year. In instances in which the disease first shows itself at a very late period, the question of acquired syphilis must always be taken into consideration.

The usual history of inherited syphilis, exclusive of those cases in which the child is born with marked lesions, is that after a few weeks or months the earlier manifestations of the disease make their appearance, such as a macular eruption or mucous patches of the mouth and tongue. At this early stage there is usually no eye or ear disease, or affection of the bones or joints. These lesions soon pass away, and there may be no further syphilitic trouble for years, or until the age of puberty is reached; when there may develop keratitis, otitis, disease of the bones or joints, or deep ulcerations in the buccal or nasal cavities. Unless the early history of the patient can be accurately learned, it may be supposed that these late manifestations constitute the first appearance of the disease. Thus, Fournier relates a case in which a man of thirty, who strongly denied ever having had syphilis, became affected with gummous ulcerations of the penis. By communicating with the patient's family physician, however, he ascertained the fact that his mother when *enceinte* with him had acquired syphilis from her husband; that at the age of two years he had had syphilitic disease of the knee-joint and peripheric ulcerations, and that when an infant he had infected with syphilis the nurse who suckled him. At the age of fourteen he had keratitis. The missing links in the history were thus furnished by the family physician. While even the diagnostic sign of the Hutchinson teeth is often absent in such cases, Dr. Sturgis expressed the opinion that in every instance of hereditary syphilis, if the history can be fully ascertained, it will be found that these later lesions have always been preceded by earlier and lighter manifestations of the disease.

DR. E. L. KEYES said that he could state with positiveness that it had not been his experience to see any instances of what could be called late hereditary syphilis. He had met with alleged cases of this character, but in all of them he was able to detect some scar or deformity which convinced him that the lesions referred to were not the first manifestations of syphilis in the system. He had followed up a number of individuals who were known to have had hereditary syphilis, and found that after various periods of latency the disease sometimes broke out again before the age of twenty-one. Before they reached the age of twenty-five, however, when crystallization of the system had taken place, the trouble had been pretty well gotten through with; and he did not recall a single instance in which a new symptom of hereditary syphilis had appeared after this latter age. Still, it is quite possible for us to believe almost anything in regard to syphilis, because it is such an irregular and erratic affection.

The character of the disease in any particular case is also largely a matter of soil; so that he did not believe in a virulent or a benign type of syphilis *per se*. The seriousness of the symptoms would depend to a great extent on the constitutional characteristics of the subject, and in this connection he referred to three brothers, all of whom had syphilis at different times, and in all of whom it produced grave lesions of the central nervous system, which, in one of them, proved fatal. Yet the third of the brothers gave the disease to a young woman, who had it in an extremely light form. The younger the subject, as a rule, he believed, the more serious the disease is apt to be, whether it is hereditary or acquired, on account of the more active changes taking place in the system during early life. Hence, the older the subject, the less serious its effects; and in the aged these are comparatively trifling.

Dr. Keyes then related the case of an infant born under his observation, in which the disease was so markedly developed that he despaired of its life. It shed its nails and had pemphigus of the soles and palms, bad snuffles, and enlarged epiphyseal extremities. He commenced treating it, however, with one-fiftieth of a grain of bichloride of mercury every two hours, night and day, and it soon began improving. At the age of six months now, it was not only alive but thriving vigorously, and it still continued to take the same dose of bichloride every four hours. In future years, if this child should have syphilitic lesions, this early history might be lost sight of, and it might, perhaps, be considered an instance of late hereditary syphilis. It is easy to see how in many instances the early manifestations of the disease may entirely escape observation or be lost sight of. The method of treatment adopted in this case was one which he had worked out some years ago at the New York Foundling Asylum, and he had always found it very satisfactory. It was his usual practice to give a hundredth of a grain of the bichloride every hour, if practicable, and he had not found that it ever produced mercurialization or diarrhœa. In fact, at the Foundling Asylum it often had a salutary effect upon the diarrhœa from which the infants are so apt to suffer.

DR. P. A. MORROW said that the subject under discussion had been comparatively neglected, and that it was only within the last few years that we had begun to appreciate how wide might be the impress of syphilis upon the organism. In many cases it is impossible to get at the history of the individual from birth, and he said he should be very much inclined to doubt whether any patient whatever who manifests the later lesions of syphilis has entirely escaped the earlier symptoms of the disease. Only that day, however, he had examined a girl of eighteen, whose reputation was above suspicion, and who was undoubtedly suffering from hereditary syphilis. She was the subject of many cicatrices, while the soft palate and palatine structures, as well as other portions of the vocal apparatus had been destroyed, and she was completely aphonic; yet, in this instance, it was impossible to get any history of syphilis in infancy.

Dr. Morrow went on to say that he could see no reason why hereditary syphilis should not continue throughout a lifetime, just as the acquired disease is often known to do. It is essentially the same affection. So far as his experience went, there was absolutely no history of the early manifestations of the disease in many cases; but this was, of course, only negative evidence, and it was contrary to his general knowledge of the course of

syphilis to suppose that in any instance the patient had really escaped these earlier manifestations. In conclusion, he referred to the case of an infant affected in much the same way as that mentioned by Dr. Keyes. It was apparently moribund, and it was a wonder that it lived at all. It did live, however, and several weeks later developed into a healthy child. Yet in this instance no medicine whatever was given. He did not wish to depreciate the value of mercury in such cases, but here the mother only was treated.

Dr. Robert W. Taylor said that his conviction was firm that there are always some manifestations in early infancy, though these may be so ephemeral and unaccompanied by distinctive action, that they leave no permanent trace. We may expect the later lesions to appear at almost any time up to about the twenty-first year. In the chapter on inherited syphilis, in Bumstead and Taylor's work, he said that he had placed the normal limit at twelve years (although, as is well known, manifestations of hereditary syphilis occasionally show themselves at a considerably later period), for the reason that he feared that other affections might be confounded with inherited syphilis, which is so comparatively rare at these later ages. Dr. Taylor said that in his work published in 1876, he was the first in America to call attention to the bone lesions of syphilis, and to bring them out of the slough of so-called scrofula. All the way up to the age of puberty we may expect the later manifestations, but when we get beyond the twenty-first year it is pretty hard to say that you are dealing with hereditary syphilis. As a rule, the activity of the lesions occurs before the tenth or twelfth year. Dr. Taylor said that he could not agree with Dr. Keyes in regard to the comparative lightness of syphilis in old people, for in his experience he had found it exceedingly severe and troublesome in such subjects.

Dr. L. Bolton Bangs said that he was in accord with the other speakers in regard to the question at issue. His own observation had been, that almost invariably by careful inquiry and investigation he was able to find some history of previous symptoms; and he mentioned a case of late tubercular syphilide of the face, in a patient twenty years of age, in which he found that there had been unmistakable signs of syphilis in early childhood.

Dr. Chapin mentioned the case of a child of four years in which syphilitic periostitis, affecting both tibiæ, appeared, apparently without any previous manifestations of the disease, as the patient had been carefully watched from birth by its parents. He agreed with Dr. Keyes as to the importance of the soil into which the syphilitic infection was introduced, and said that he had known of many syphilitic infants with snuffles and mucous patches who were fat and robust, and seemed to thrive on the disease. As to the later lesions, occurring in individuals beyond the age of ten or twelve years, he thought they might as well be called scrofula as syphilis. If there were no typical lesions of syphilis present, it was his practice to put the patient on codliver oil and other tonic treatment, as he was unable to tell whether the trouble was really syphilitic or not.

Dr. Alexander S. Hunter related the case of a woman aged eighteen who suffered from extensive destruction of the nasal bones and soft palate, which he believed to be due to hereditary syphilis. He had had the opportunity, however, of interrogating those who had been with the patient from infancy, and they positively stated that there had been no manifestation of the disease until she was fifteen. Still, it was, of course, certainly possible that they might be mistaken on this point.

Dr. L. Emmett Holt related cases in his experience and said that he thought it the easiest thing in the world for the earlier manifestations of syphilis to be overlooked. He then called attention to the importance of enlargements of the epitrochlear glands as a diagnostic sign of the disease. Although this condition may be due to other causes, in his experience very few cases of syphilis occur without the enlargement of these glands.

The President said that when syphilis occurs at birth it is not always easy to recognize positively. There is sometimes great difficulty in distinguishing between a syphilitic and a rachitic bone, or rather cartilage, and particularly when the ribs are affected. If the difficulty is great then, at this early period, it is still greater later on. It is a fact that where a number of children are born in a syphilitic family, the manifestations are apt to become less and less marked in each successive child, and the disease may at last be indistinguishable from the symptoms of so-called rachitis or so-called scrofula.

In regard to the age at which hereditary syphilis first makes its appearance, it is a peculiar fact that the cases first occurring in adolescents or adults are all reported by the older writers, of twenty-five, thirty, or forty years ago. It does not appear that any of the later writers mention any such cases. Thus, Burke says that he never saw one, and Diday, who said the same thing thirty years ago, is still of the opinion that such cases do not occur. Having referred to other authorities, Dr. Jacobi said that probably one reason why the earlier manifestations were apt to be overlooked in former years was on account of the universal use of calomel (an antisyphilitic remedy) in all the diseases of children. Personally, he said he had seen a few cases of late hereditary syphilis. The oldest of these patients was thirteen when the late lesions presented themselves; but in this instance it was easy to trace the disease back to infancy.

Dr. Sturgis said that he had for the most part reserved an expression of his own opinion until the close of the discussion. What he meant by the late lesions of hereditary syphilis were those occurring after the age of five years, and he believed that such late manifestations did not occur without previous symptoms. He mentioned the case of a patient of seventeen who was sent to him for diagnosis with a cold inflammation of the knee-joint, which had resisted all forms of treatment. On careful examination he was able to detect traces of an old keratitis and otitis. The children in whom these late lesions are found are apt to be born apparently healthy, and when the earlier manifestations do occur they may escape notice and receive no treatment. It is in the contracted cases that the later lesions are most liable to make their appearance. At the age of five or six years we are likely to have punctate interstitial keratitis and disease of the joints, ears, etc., and nothing will be found to do any good until iodide of potassium is resorted to. Under this treatment the child usually gets well rapidly. At ten there is apt to be another outbreak of trouble, and about the age of puberty the most serious explosion usually occurs. After the age of twenty-five the disease will generally be found to be acquired. If a patient over

this age presents himself with the earlier symptoms of syphilis we can always suspect that the disease is acquired. The first manifestations of the inherited disease are most likely to show themselves within three months after birth, and always do so within twelve months.

PHILADELPHIA NEUROLOGICAL SOCIETY.

Stated Meeting, February 27, 1888.

The Vice-President, Charles K. Mills, M.D., in the Chair.

Dr. William Osler reported the following case of

ENLARGEMENT AND CONGESTION OF THE RIGHT ARM FOLLOWING EXERCISE OF ITS MUSCLES.

J. B., aged forty-eight, white, a robust, vigorous-looking man, applied at the University Hospital on November 4, 1887, complaining of swelling of the right arm when he worked.

His family history was good, and he had always been healthy with the exception of several attacks of sciatica, which he had suffered with lately. He was married and had five children, all healthy. When he was young he had had smallpox. He entered the Navy in 1861 and left it in 1863, and has been a storekeeper ever since. He had gonorrhœa in 1858, but there was no history of syphilis. About two days before he applied at the hospital he began to work as a carpenter, but had to give it up in two or three days on account of the swelling in the right arm. The arm also became tender and blue, but on raising it over his head the swelling and dark color would disappear. There was no history of sprain or injury, and otherwise he appeared to be in excellent health.

Before exercise the measurements were as follows: Right arm, 11.4 inches; forearm, 11 inches; left arm, 10.25 inches; forearm, 11 inches.

The patient was a well-developed, well-nourished man, with chest well formed, sternum a little prominent over manubrium, subcutaneous veins somewhat prominent, those over the anterior aspect of the left shoulder more than the right. His pupils were equal. The heart apex beat was just visible below and inside the nipple. There was dulness at the lower border of the fourth inside nipple line, and the right border of the sternum. The sounds at the apex were clear; first sound at the base somewhat feeble; second distinct, not specially ringing or metallic; and not more distinct toward the right than the left clavicle; no pulsations in the vessels of the neck and no murmur. Radials were equal; no atheroma; no increased tension, and no stiffness in the vessel wall were apparent. The right arm and hand looked larger than normal; and when at rest the skin was the same color in both; the muscles were well developed; the panniculus was the same on both sides. There was no distention of the veins, and no œdema. The brachial artery could be easily felt, and the axillary artery was not very deep on either side. No difference in the pulsations of the two axillary arteries could be detected, and no murmur could be heard in either.

After exercise the measurements were as follows: In a few minutes the right arm measured 11¾ inches; forearm, 12½ inches. It became livid; there was capillary injection, and the distended veins felt like cords. The radial pulse was only just perceptible. Auscultation of the axillary artery gave a distinct murmur not audible on the other side. When the arm was held up the congestion would disappear in a few minutes. There was a feeling of fulness, but no pain. Deep percussion in the upper axillary region was negative. There was no enlargement of the axillary glands; the expansion at the apices was equal. No pain was experienced on deep pressure in the neck. The side of the face did not flush with the arm, and the opposite side was not affected. Percussion was the same on both sides behind.

Dr. Osler wished to place this case on record, as it presented very unusual features. He thought at first that the condition was due to obstruction, perhaps from pressure, on the subclavian or axillary veins, or possibly occlusion with reëstablishment of a collateral circulation sufficient for the ordinary blood flow which occurs during active use of the muscles. There was, however, no evidence of any such obstruction, nor were the veins of the shoulder-girdle distended. The glands were not enlarged; there was no subclavicular dulness, or evidence of disease at the right apex. The condition had remained unchanged during the four months in which the patient had been under observation. He was now more inclined to believe the condition one of faulty innervation of the vessels of the arm during exercise, a defect in the local regulating mechanism controlling the supply and outflow of the blood, the circulation of which is, as we know, enormously increased by contraction of the muscles.

Dr. James Hendrie Lloyd presented the following

REPORT OF A CASE OF RAPIDLY FATAL EXOPHTHALMIC GOITRE.

On August 12th he was summoned to a case which was described as cholera morbus. The patient was a single woman, aged thirty-nine, who had been suffering for some hours with diarrhœa and vomiting. Pulv. opii and plumbi acetat. were prescribed. On the following day the diarrhœa was checked, but obstinate, persistent vomiting continued. This vomiting was quite remarkable, allowing not a morsel of food or even a small quantity of water to remain in the stomach. A careful physical examination failed to detect any direct cause for this. There was slight tenderness in the epigastrium, but no hardness or evidence of any growth; no enlargement of the liver or spleen; no evidence of hernia; no abdominal pain, or any tympanites. A very marked derangement of the vascular system was, however, detected. The whole abdominal aorta to its bifurcation was throbbing intensely, with a pulsation somewhat expansile. The heart's action was rapid, but there were no intracardial murmurs. It was now observed that the patient's eyes were very prominent and staring, which symptom had escaped observation at the first visit on the preceding evening (possibly due to the poor light in the room). Further examination revealed a much enlarged and rather soft thyroid gland.

Careful inquiries were now made of the parents and near relatives about the patient's previous health. They had regarded her as a perfectly healthy woman up to this attack. They had, to be sure, noticed the altered appearance of her eyes, but it had not made much impression upon either them or her, and had not been of long duration. She had had a spell of illness about six months previous, the exact nature of which he could not

determine, but it had been accompanied with some irritability of the stomach and prostration (as she recollected). Since then she had been apparently healthy, bright, and active; had not complained of dyspnœa; and had been out on the day of the onset of the so-called "cholera morbus," for which he had been called to her. The vomiting continuing as the most distressing symptom, a carefully regulated diet was ordered, and tinct. ipecac. gtt. ij was ordered every hour. The pulse was beating as high as 100 per minute.

The patient passed a restless second night. In the morning the vomiting was somewhat relieved, but not gone. The prostration was growing worse, and the case had assumed a threatening aspect. The pulse had risen to 170. Cyanosis of the hands and feet was observed. Consultation was now held with Dr. W. G. Porter, who concurred in the diagnosis. Calomel was ordered in one-half grain doses every hour; ex. opii, gr. ½, by suppository every two hours until quieted; digitalis, which had not been given because of the extreme gastric irritability, was also determined upon; brandy, as much as the stomach would bear. At the evening visit the pulse was found, as nearly as it could be counted, 70 to the third of the minute, 210 per minute. The vomiting had ceased. Ordered one-half ounce of milk, with which tr. digitalis, ♏. x, was to be put, every half hour, the digitalis to be given only every hour after the fourth dose. Collapse was imminent; the patient had had several fainting spells. On the morning of the third day the pulse had fallen to 160, apparently under the digitalis. Dr. Porter again saw the patient. Ex. bellad., gr. ⅓, was added to the suppositories. Later that day the patient's pulse again failed. At the last visit the heart was beating in a very tumultuous way, and no pulse was perceptible at the wrist. The mind was perfectly clear. She died at the end of the third day of her illness.

The autopsy in this case was, unfortunately, not complete, owing to the jealousy of the family, who refused to allow the skull-cap to be removed. He therefore reported it more for its clinical interest than for any light it throws upon the pathology of this interesting but obscure disease. The examination was made by Dr. Dock, in the presence of Dr. Porter, Dr. J. H. Musser, and himself. The heart was a little dilated in the left ventricle, and slightly hypertrophied. The lungs, kidneys, and suprarenal capsules were normal; the liver was not abnormally fat. The stomach was slightly congested, due probably to the excessive vomiting. There were no other abnormal appearances in the chest or abdomen, which were alone opened.

It may be noted that this patient had had urticaria, a fact recorded by Dr. Bulkley[1] in two cases of the same disease. The special interest which attaches to this case, however, is its very acute character and rapidly fatal termination; for while there was some evidence of the disease having been making insidious approaches for several months, it had not impressed its presence upon the notice of either the patient or the family until it culminated in a violent crisis, which quickly deprived the woman of her life.

Dr. Wm. Osler said that these acute cases of exophthalmic goitre are rare. Were any mental symptoms present? Recently, in Dr. Henry's ward in the Philadelphia Hospital, was a case of this disease, in which acute symptoms suddenly developed, and death took place with marked mental trouble.

Dr. J. H. Lloyd said that in his case the mind was perfectly clear, nor was there the slightest hysterical character about the symptoms. The patient was naturally much agitated over her condition.

Dr. W. B. Jameson made the following remarks on a case of

CARDIAC ANEURISM FROM AN INSANE MAN.

The heart which he exhibited was from an insane man who died in Dr. Lloyd's wards in the Insane Department of the Philadelphia Hospital; and it was through his courtesy that he was able to present it. The man was fifty-six years of age, a native of Switzerland. He was probably a priest, but for several years before admission to the hospital was engaged as a teacher. He had no friends in this country, and it was impossible to obtain a definite history. He was arrested on the streets and sent to the hospital. When admitted he was in an excited state; had evident delusions of persecution, believed that his food was being poisoned, and also had hallucinations of sight and hearing, and would often sit for an hour at a time talking to some imaginary individual. At times he was excited and would go about the wards declaiming to imaginary audiences. He would often preach, and sometimes chant. His physical condition was good. No physical lesions were discovered on admission. The heart sounds were clear, distinct, and without murmur. It was thought that there was possibly a pleural friction sound, but this was not definitely determined.

When Dr. Jameson went on duty in the Insane Hospital six months ago, the man was apparently in perfect health. He was quiet, speaking pleasantly when spoken to, but nothing more. He was well advanced in dementia, although perfectly cleanly in his habits. One day while Dr. A. A. Stevens and Dr. Jameson were in an adjoining ward, they were summoned to see this man, who was said to be dead or dying. They found him lying on the floor absolutely pulseless, face white, extremities cyanotic and cold, and respiration gasping. Brandy was given and ether hypodermatically. He was then put in a bath with the temperature of the water at about 117°. He shortly improved, became quite rational, and talked clearly. He complained of no pain whatever. He was kept in the bath three-quarters of an hour, when he began to sink, and was taken out and soon died.

Three hours after death the autopsy was made. The brain showed nothing special. There was nothing of interest found in the abdominal cavity. When the first costal cartilage was cut, blood gushed out, rising a distance of at least two inches. The whole mediastinal space was filled with fluid and partially coagulated blood. Extensive pleural adhesions, more particularly on the right side, were found. The space that was left was filled with blood. The total quantity was estimated at about two pints. The aorta was examined carefully with the parts in place, but nothing abnormal was found. The pericardial sac was found to be one-third filled with fluid blood. An aneurism was found at the apex of the right ventricle, and just at the septum there was a small opening where a rupture took place. The opening in the pericardium was not positively located.

[1] Hammond: Diseases of the Nervous System, p. 812.

In looking over the literature, Dr. Jameson found but one or two references to the subject. One case of rupture of the left ventricle was reported in the *American Journal of Insanity* for January, 1885. In this article reference is made to three other cases which had been reported in the *Edinburgh Medical Journal* for February, 1884. In all these cases the patients were about seventy years of age.

In this case there was no atheroma of the aorta. There was an ulcerated condition along the lateral border, also on a spot about the epicardial surface, three-fourths of an inch broad by one inch long, which presented the same appearance as the aneurism. Whether this spot was connected with the ulcer inside he could not say.

DR. WM. OSLER said that it is very unusual to find aneurism of the right ventricle of the heart. This condition is most common on the left side. The majority of aneurisms are the result either of local weakening, due to pericarditis, which is the less frequent case, or to a fibroid condition of the left apex. There is one other condition which may lead to the rapid production of aneurism of the heart, viz., myomalacia or anæmic softening, due to arterial changes. He would suggest that sections made from this locality might throw some light on the nature of the condition. The fact that we have in the immediate vicinity of the aneurism another spot of disease, would seem to point in this direction.

CORRESPONDENCE.

THE GALVANO-CAUTERY IN THE TREATMENT OF ENLARGED TONSILS.

To the Editor of THE MEDICAL NEWS,

SIR: In THE MEDICAL NEWS of March 10th, I notice the report of a paper read by Dr. Frank Hamilton Potter before the Medical Society of New York, on "The Galvano-cautery in the Treatment of Enlarged Tonsils." It embodies, I think, the experience of the majority of those who have *had* experience in the matter. There has lately been a great deal of literature on the subject in both home and foreign journals, but there are a few points deserving of mention which I have not seen dwelt upon sufficiently.

1st. As to pain. The fact is that while many tonsils may seem utterly devoid of sensation when hypertrophied, others, on the contrary, are quite sensitive to the application of the hot wire. Often, in the same patient, one tonsil may be cauterized freely with total immunity from pain, while the other is so sensitive as to require the application of cocaine, which, I think, should be avoided in the throat, if possible. I think most operators will agree with me that it is not always a "painless operation" as Dr. Potter sums up.

2d. As to the number of ignipunctures made at one sitting, I had the advantage of Dr. Knight's personal direction before he read his paper at the last meeting of the American Laryngological Association. At that time and since then, I think, he has limited the number of punctures to at most five or six at one sitting. (I only write from memory, and may be mistaken.)

Since then it has been my custom to regulate the number of punctures almost entirely by the size of the tonsil and the sensitiveness of the patient to the application of the hot wire. Whenever I have a comparatively insensible organ I make enough punctures to cover the whole tonsillar surface with a slough, even sometimes burning away small projections of tissue altogether. I have used the cautery, with three or four exceptions, for the last nine months in every case of enlarged tonsil I have seen, that number being the proportion usually seen in a throat clinic, for that time averaging 1200 to 1500 new patients yearly, and many times in private practice. With possibly one or two exceptions I have never seen any serious reaction. Occasionally the patient's throat would be very sore for part of the next day, but this has seldom lasted more than two days at the most. One case, I remember, complained of a sore throat for as long as five days. Another had an intervening quinsy, which, however, did not begin until two days after the operation, and may have been simply a coincident. Usually, most reaction is observed in those with sensitive tonsils even if only slightly burned—and mostly after the first sitting—the succeeding operations being followed by little pain.

Of course, this radical procedure can only be adopted at first when the tonsil is still large, because after most of the tonsillar tissue has been destroyed a sensitive area is reached near the normal mucous membrane, where pain always follows any deep or extensive cauterization. When this stage is reached, longer intervals should be observed, as there is always more or less infiltration of the surrounding mucous membrane which will disappear of itself if left untouched.

3d. As to its use in children. Lately I have ceased operating in patients under the age of twelve with the cautery. It is nearly always unsatisfactory. "Kindness and patience" will often lead the little ones to submit for one or two sittings, by which time you have changed the size and shape of the tonsil so that a tonsillotome can only be used with difficulty, and ignipuncture has become of exceeding difficulty owing to the want of control that even the most tractable child has over its pharynx. You now have a ragged mass of tissue between the faucial pillars full of holes and lodging places for food and secretions.

A tonsillotome, a strong assistant, and a sensible guardian of the child are all a moderately deft operator needs to settle the whole affair of enlarged tonsils in two minutes, without "general anæsthesia" and the danger of blood in the trachea of an insensible patient. I think there are no cases on record of serious—at least fatal—hemorrhage under the age of twelve. I believe that those who see a large number of cases of enlarged tonsils each year will soon discard tonsillotomy in adults where ignipuncture is possible. In many cases the latter is almost an absolute necessity owing to the diffused condition of the tonsillar tissue, and also, rarely, to the size of the mass to be removed.

4th. As to the number of sittings. I have never met with a case in which the hypertrophied condition was not removed by at most fifteen sittings if properly carried out. Usually half the number is sufficient.

To conclude, recurrence of the hypertrophy is occasionally seen where the tonsil has not been completely removed, or at least restored to its normal proportions. When the two operations of ignipuncture and tonsillotomy are explained to the patient with the advantages and disadvantages of each, I have yet to see the patient

who preferred the latter, though one after submitting to both said he preferred tonsillotomy.

JONATHAN WRIGHT, M.D.

73 REMSEN ST., BROOKLYN, N. Y.
March 12, 1888.

NEWS ITEMS.

The Illness of the Emperor of Germany.—The *British Medical Journal* of March 10, states that it learns by special telegram from San Remo, that the general condition of the Emperor Frederick is now very good. The irritation of the windpipe that was so troublesome for some time, has almost entirely disappeared, but there is some increase in the swelling within the larynx. We may add, that we are able to confirm this comparatively favorable account by independent information which we have received from a perfectly trustworthy source. We are in a position to state that neither Sir Morell Mackenzie nor Mr. Hovell is inclined to share the pessimistic views recently made public, though they do not, of course, deny the possibility of the disease proving to be cancer.

With regard to a rumor which has been largely current in society, and which lately found most unseemly expression in a French contemporary, we have the fullest authority to deny, in the most emphatic manner, that there is any ground for such a suspicion. We may repeat that the recent sufferings of the illustrious patient have been almost wholly due to the irritation caused by an ill-fitting tracheotomy tube. The operator, as was perhaps natural under the circumstances, appears to have been rather nervous, and the windpipe was opened some way to the right of the middle line; hence the difficulty of finding a suitable tube. Sir Morell Mackenzie, assisted by Mr. Hovell and Dr. Evans, the well-known dentist of Paris, spent the greater part of one day in constructing a tube of a shape specially adapted to the requirements of the case. Since this has been worn the Emperor has been more comfortable in every way; he has been able to sleep, the cough has diminished, and the expectoration has almost lost the blood-stained character which excited so much alarm.

It is satisfactory to see from the official bulletin lately published in the *Reichsanzeiger*, that the medical men are now in substantial agreement as to the nature of the disease. We do not think, however, that the inference which has been drawn from this in certain quarters, that Sir Morell Mackenzie has abandoned his recently published opinion on the subject, and adopted the less favorable view of some of his colleagues, is altogether warranted. Although the result of Professor Waldeyer's microscopical examination has not been published, we have reason to believe that it is such as to admit of a favorable interpretation.

An Illustrated Catalogue of the Army Medical Museum.—Dr. Billings, of the Army Medical Museum, will signalize the removal to the new building near the National Museum by the preparation of an illustrated catalogue. It will contain drawings of all the crude and wet specimens of tumors, cancers, gangrenes, etc., and other objects on exhibition in the museum, besides micro-photographs of morbid tissues prepared by Dr. W. M. Gray, the microscopist of the Surgeon-General's Office. Each picture will be accompanied by a short description of the object illustrated, but there will be no discussion of theories. The work, when completed, will constitute a complete pathology, and will be a most valuable text-book for students and physicians.—*Science*, March 16, 1888.

Successful Disposal of Garbage at Milwaukee.—Martin, Commissioner of Health, for Milwaukee, writes to the *Sanitary News* of March 10, 1888, reporting the success of the disposal of garbage by cremation, as follows:

Perhaps Milwaukee is not so favorably situated as some of our sister cities for the safe disposal of our refuse material, and that may be one reason why we have been forced to take vigorous measures to consume ours. Other municipalities have entered on a course of experiments involving large sums of money, and will, at the end of these experiments, be no nearer the solution of the problem than when they were first undertaken. With us it is quite different. Last summer we found that fully one-half of our garbage was water that could be, and was, extracted by a powerful press, and, as we know of no better or cheaper method of getting rid of this water, than by evaporation, and as we do not expect that garbage like ours will burn without fuel, so our furnace was erected and every day, for more than five months, our garbage has been consumed to a dry, inodorous ash; with us, it is no longer an experiment, but an accomplished fact, and we claim to be the first city that is to-day destroying her refuse material by fire. A test of the cost of consuming the garbage was made on December 27th, with the following result: The amount received and consumed was 40,215 pounds, and the fuel required was 5000 pounds, being 4.3 cents per hundred pounds of garbage consumed, a result highly gratifying when we consider that on that date there was a large quantity of snow and ice mixed with the garbage. This department entered into an agreement for three years with the contractor to burn all garbage delivered at the furnace by order of this office, being that collected by men employed for that work. The wholesale houses, grocers, commission houses, and others of that class, take their refuse to the same place. The contractor is also required to burn all small dead animals, and the furnace is in actual operation during this season, the worst of the whole year, only from eight to ten hours daily.

The Adirondack Cottages, at Saranac Lake, New York, for the treatment of pulmonary diseases, in its third annual report, presents a very gratifying record. During the year, fifty-one patients have been treated, with the following results: no deaths have occurred; eleven have lost ground more or less rapidly, most of them having returned to their homes; twelve have been slightly benefited, while twenty-three have so greatly improved as to be able to resume their various occupations, and five have been cured. On December 11 the weighing of patients showed the highest average gain yet noted. For seventeen patients (the entire number then in the institution who had been under treatment over two and a half months), the average gain per person was thirteen and one-eighth pounds.

Practical Courses in Dermatology at Hamburg.—We are requested by Dr. Unna, of Hamburg, to announce that he will begin a course in dermatology, for physicians, on April 1, 1888. This instruction will embrace the his-

tology, bacteriology, diagnosis, and therapeutics of skin diseases, and will be illustrated by the resources of Professor Unna's clinic and policlinic. Further information may be obtained by addressing Dr. P. G. Unna, Dammthorstrasse 15, 1., Hamburg, Germany.

A Sanitary Convention will be held at Manistee, Michigan, June 6 and 7, 1888, under the auspices of the State Board of Health.

The Decision by the Court of Claims in the case of Major John S. Billings, surgeon, United States Army, effectively disposes of the pretension of the accounting officers of the Treasury Department to dispute all orders of heads of departments involving the expenditure of money. Surgeon Billings was in 1881 and 1884 sent to Europe by the Secretary of War as a delegate to the International Medical Congress. He made a charge for mileage for distances travelled in Europe. The Court of Claims holds "that if there were any doubt of the authority of the War Department to order Major Billings to travel abroad on the public business intrusted to him, the long-continued practice of sending officers abroad on like business and paying their mileage from the Treasury through the accounting officers without objection would be strong reason for upholding the legality of such orders. But we do not think the question admits of doubt. The orders were legal and cannot be controverted by any other executive branch of the Government." The court further holds in specific terms that "the accounting officers of the Treasury have not the burden of responsibility cast upon them of revising the judgment, correcting supposed mistakes, or annulling the orders of the heads of departments." Again the court says: "It would be a novel principle to refuse payment to the subordinates of a department because their chief, under whose direction they had faithfully served the public, had mistaken his own powers and had given an erroneous construction of law."

A Prize for the best Portable Hospital.—A prize has been offered by the Empress of Germany, for public competition, of about $1500 for the best essay on the furnishing and carrying on the work of a portable hospital for sick and wounded persons; there will be also three gold and nine silver medals. The award will be made next September at the Brussels Exposition, and the German Association of the Red Cross will have the management of the competition. The competitors must send in their exhibits before August 15th. This is the second grand prize given by the Empress in this direction of improving field-hospital service; the former one having been awarded in 1885 for portable hut-hospitals.—*British Medical Journal*, February 25, 1888.

The Pollution of Streams.—The *Sanitary Engineer* of March 10, 1888, writes as follows on this subject:

The first and main consideration is as to whether the stream is or is not used as a source of drinking-water supply. If it is to be so used, it is certain that our present knowledge as to the limit of sewage impurity which may be considered permissible is very vague and wanting in scientific precision, and that there is much need of a series of careful observations on the effect of time and distance of stream-flow on diluted sewage, and especially on such pathogenic bacteria as the sewage of a community is liable to contain. The action of the ordinary bacteria of a sewage effluent is not harmful, but beneficial, and it is probable that there are other forms of bacteria, not contained in large numbers in ordinary sewage, but which are specially valuable as purifiers of such material and which exist in great abundance in those soils in which oxidation and nitrification are rapidly produced.

It is quite possible that these oxidizing bacteria might be cultivated in large quantities and added to sewage, but to enable them to flourish and do their work it is necessary that they should have a large supply of oxygen. This they have in soils which are not allowed to become too moist, but they do not have it in water, unless by agitation or in some other way air is mingled with the water.

Even with our present imperfect knowledge there is one fact which is tolerably clear, and that is that any stream of small or moderate size which lies in the midst of a populous and growing district is polluted, and will probably become more polluted, that this process is one of gradual increase, and that while we may not be able to predict a definite time in which it will become a nuisance or dangerous to health, we can see that it will become so sooner or later.

Typhoid Fever and Drinking Water in Vienna.—The *Sanitary Engineer* writes that the evidence is very strong that typhoid fever in Vienna has been connected with the water-supply, and that those who make use only of the present general supply run very little risk of taking this disease. Cases are now rarely seen in the hospitals, and when they do come it is almost invariably from some suburb to which the general supply has not yet been extended. Dysentery has also nearly disappeared, no deaths from this cause having been reported for the years 1881–86, and the whole statistical record gives excellent evidence as to the good effects produced by an unpolluted water-supply.

The Hygiene of Railway Operatives.—The Directors of the Great Northern Railway have recently issued an order to their firemen and engine-drivers which should be the initiation of similar regulations throughout the various railways in the country. No fireman or engine-driver is to be allowed to go on duty unless he has had at least nine hours' rest. Such an instruction should not be necessary, but being necessary, its issuance is no less a boon to the men than a source of safety to the public. —*Sanitary Engineer*.

The Contamination of Water by Lead.—There has been quite a lead-poisoning scare in Sheffield, England, which has called out the usual number of theories and suggestions. Among others Dr. Sinclair White has proposed a simple remedy—namely, filtration through lime—which seems likely to be adopted.

The *Journal of Gas-Lighting* directs attention to a letter recently addressed to the *Sheffield Telegraph* by Mr. Alfred H. Allen, F.I.C., F.C.S., President of the Society of Public Analysts, in which some suggestive remarks are made. The proportion of lead which is generally considered to render water seriously objectionable is one-twentieth of a grain per gallon; but Mr. Allen says there is some reason to believe that in cases

in which serious effects have been observed in Sheffield, the proportion has considerably exceeded this limit. It must not be supposed, however, that there is any danger in drinking a glass of water containing such a minute proportion of lead. It is not the single dose or a dozen doses which will produce any ill effects, but the constant use of such contaminated water. Lead is a cumulative poison, and each successive dose becomes stored up in certain organs of the body until the poisonous effects ensue. Further, it must not be supposed that every one is equally susceptible to the effects of lead, there being a great difference in this respect.

Mr. Allen adduces a striking instance, which came within his own experience of the way in which lead poisoning may occur. A year or two since a member of his family suffered from symptoms which her medical adviser considered to be due to lead-poisoning. The water drawn from the tap the first thing in the morning contained half a grain of lead per gallon, and about half this proportion after being allowed to run. By passing the water through a particular description of carbon filter every trace of lead was removed; but tea made from such pure water was sometimes found to contain 0.75 grain of lead per gallon. Analysis showed that the tea as bought was free from lead, and for some time Mr. Allen was puzzled to account for its presence. It was afterward found that the fur, or deposit, inside the kettle contained a considerable proportion of lead, some of which became dissolved in the water boiled in it. The kettle being replaced by a new one, the symptoms of lead-poisoning disappeared under proper treatment. He attributed the lead in the deposit to a servant having habitually filled the kettle from the hot-water tap, for hot water, it appears, acts on a lead pipe much more vigorously than cold.

It is reported by the Medical Officer of Health (Dr. A, Mackintosh) that from 100 to 150 more people are suffering from lead-poisoning in Chesterfield, England.—*Sanitary Engineer.*

Face Masks, Rouge, and Skin Washes.—The *American Analyst* of March 1, 1888, reports that of the numerous "face masks," "beauty masks," "complexion balms," "medicated pastes," "blooms of youth, beauty, or loveliness," "Lola Montez secrets," not one is good in any respect. The very best is without value. From this they range down to the depths of an injuriousness and ghoulish action. The best consist of an oil, fat, or glycerine, with some perfume, and a trifle of gum benzoin, camphor, or other drying substance. These are simply nasty. Their action is the same as of lard or butter smeared thickly over the face of the user. The rest are dangerous as well as disgusting. They contain the same ingredients as the face powders denounced, and are even more pernicious in their action. Lead colic, lead paralysis, mercurial ulcers, arsenic sores, boils, carbuncles, abscesses, putrid glands, salivation, sudden baldness, and even more serious ills, can be traced to their use, and will invariably accompany that use as long as the human body remains as it is to-day.

Of the rouge preparations, those made from cochineal and madder are harmless. All others are bad, very bad, and horrible. The "eau de vinaigre," "rouge vinaigre," "camphor wine," "red pepper wash," "capsicum elixir," and the like, which depend for their effect upon irritating the nerve corpuscles, are unobjectionable to the physician and the chemist. The new preparations, which are solutions of aniline and other coal tar colors, are poisonous and should be prohibited by law.

There is little or nothing to be said against the washes used to remove pimples and blackheads. They are usually made by dermatologists of good standing, and do their work properly, and in a reasonable time. It is far better, however, to depend upon a fine toilet soap or dilute ammonia, gentle but persistent rubbing, the Turkish or Russian bath, and a piece of lemon. A two weeks' course of the latter will improve any complexion better than all the washes extant, and, more than that, will correspondingly improve the general health.

Disinfection by Sunflowers.—It has been stated that since the sunflower has been cultivated on certain swamps of the Potomac, malarial fever has decreased. At the mouth of the Scheldt, in Holland, it is stated that similar results have been observed. The sunflower emits large volumes of water in the shape of vapor, and its aromatic odor, as well as the oxygen it exhales, may have something to do with the sanitary influence in question.

The Contagion of Leprosy in Minnesota.—The State Board of Health of Minnesota gives out the statement by Dr. Grondold, of Norway, Minn., that "no case of leprosy has ever originated in Minnesota by contagion, and that of all the children of lepers living here, not one has exhibited any signs of the disease."

The Part played by the Skin in "Catching Cold."—The part played by the skin in the contraction of colds, and such diseases as begin with a cold, is well worthy of being scientifically studied, especially at a time when the general acceptance of a germ theory in relation to these diseases has upset all previously formed opinions. This part has been made the object of study by Dr. E. Lier, of Creuznach, and his investigations form an interesting chapter in the recent number of the *Monatsch. f. prakt. Dermatologie.* His conclusions, which may prove suggestive if not instructive, are as follows: 1. The skin renders colds possible simply as the organ of temperature sense, and its action is reflex. 2. The histological and physiological changes in the skin are reflex phenomena. 3. The disposition to colds depends on the degree of the resisting power of the skin. Further consequences are: that the best prophylaxis against colds depends on the skin, and may be brought about by skin gymnastics and stimulating baths. 4. The treatment of these diseases by diaphoretics is not causal, but symptomatic. A rational treatment of febrile diseases consists in the employment of such agents as act on the central organs, morphia, chloral, digitalis, warm or tepid baths, camphor, musk, cold douches, and in the case of infective diseases, antiseptics. He further assumes that where the predisposition to colds is marked, there must be some disease of the skin at the bottom of it all, the symptoms and pathology of which it should be the aim of investigators to discover.—*Medical Press*, February 28, 1888.

Dangers Connected with the Use of Electricity in Medicine.—Steavenson, electrician at St. Bartholomew's Hospital, warns against the careless use of electricity, in the *Provincial Medical Journal* of March 1, 1888, as follows:
